CHAPTER

ONE

WELCOME TO SCIKITLEARN

11 Installing scikitlearn

Note If you wish to contribute to the project it's recommended you install the latest development version

111 Installing the latest release

Scikitlearn requires

- Python 35
- NumPy 1110
- SciPy 0170
- joblib 011

Scikitlearn plotting capabilities ie functions start with " plot " require Matplotlib 151 Some of the scikit learn examples might require one or more extra dependencies scikitimage 0123 pandas 0180

Warning Scikitlearn 020 was the last version to support Python 27 and Python 34 Scikitlearn now requires Python 35 or newer

If you already have a working installation of numpy and scipy the easiest way to install scikitlearn is using pip
pip install U scikitlearn

orconda
conda install scikitlearn

If you have not installed NumPy or SciPy yet you can also install these using conda or pip When using pip please ensure that binary wheels are used and NumPy and SciPy are not recompiled from source which can happen when using particular configurations of operating system and hardware such as Linux on a Raspberry Pi Building numpy and scipy from source can be complex especially on Windows and requires careful configuration to ensure that they link against an optimized implementation of linear algebra routines Instead use a thirdparty distribution as described below

scikitlearn user guide Release 0.21.3

If you must install scikitlearn and its dependencies with pip you can install it as scikitlearnalldeps. The most common use case for this is in a requirements.txt file used as part of an automated build process for a PaaS application or a Docker image. This option is not intended for manual installation from the command line. Note: For installing on PyPy, PyPy3v5.10, NumPy 1.14.0 and scipy 1.1.0 are required. For installation instructions for more distributions see other distributions. For compiling the development version from source or building the package if no distribution is available for your architecture see the Advanced installation instructions.

1.1.2 Thirdparty Distributions

If you don't already have a python installation with numpy and scipy we recommend to install either via your package manager or via a python bundle. These come with numpy, scipy, scikitlearn, matplotlib and many other helpful scientific and data processing libraries.

Available options are:

Canopy and Anaconda for all supported platforms.

Canopy and Anaconda both ship a recent version of scikitlearn in addition to a large set of scientific python library for Windows, Mac, OSX and Linux.

Anaconda offers scikitlearn as part of its free distribution.

Warning: To upgrade or uninstall scikitlearn installed with Anaconda or conda you should not use the pip command. Instead:

To upgrade scikitlearn:

conda update scikitlearn

To uninstall scikitlearn:

conda remove scikitlearn

Upgrading with pip: install U scikitlearn or uninstalling pip: uninstall scikitlearn is likely to fail to properly remove files installed by the conda command.

pip upgrade and uninstall operations only work on packages installed via pip install.

WinPython for Windows

The WinPython project distributes scikitlearn as an additional plugin.

1.2 Frequently Asked Questions

Here we try to give some answers to questions that regularly pop up on the mailing list.

2 Chapter 1: Welcome to scikitlearn

scikitlearn user guide Release 0.21.3

121 What is the project name a lot of people get it wrong
scikitlearn but not scikit or SciKit nor scikit learn Also not scikitslearn or scikitslearn which were previously used

122 How do you pronounce the project name
syk-it learn sci stands for science

123 Why scikit
There are multiple scikits which are scientific toolboxes built around SciPy You can find a list at <http://ssci.kits>
appspot.com/scikits Apart from scikitlearn another popular one is scikitimage

124 How can I contribute to scikitlearn
See Contributing Before wanting to add a new algorithm which is usually a major and lengthy undertaking it is recommended to start with known issues Please do not contact the contributors of scikitlearn directly regarding contributing to scikitlearn

125 What's the best way to get help on scikitlearn usage
For general machine learning questions please use Cross Validated with the machinelearning tag
For scikitlearn usage questions please use Stack Overflow with the scikitlearn andpython tags You can alternatively use the mailing list

Please make sure to include a minimal reproduction code snippet ideally shorter than 10 lines that highlights your problem on a toy dataset for instance from sklearn.datasets or randomly generated with functions of numpy random with a fixed random seed Please remove any line of code that is not necessary to reproduce your problem The problem should be reproducible by simply copy-pasting your code snippet in a Python shell with scikitlearn installed Do not forget to include the import statements

More guidance to write good reproduction code snippets can be found at <https://stackoverflow.com/help/mcve>

If your problem raises an exception that you do not understand even after googling it please make sure to include the full traceback that you obtain when running the reproduction script

For bug reports or feature requests please make use of the issue tracker on GitHub

There is also a scikitlearn Gitter channel where some users and developers might be found

Please do not email any authors directly to ask for assistance report bugs or for any other issue related to scikitlearn

126 How should I save export or deploy estimators for production

See Model persistence

12 Frequently Asked Questions 3

scikitlearn user guide Release 0213

127 How can I create a bunch object

Don't make a bunch object They are not part of the scikitlearn API (Application Programming Interface) Bunch objects are just a way to package so
numpy arrays As a scikitlearn user you only ever need numpy arrays to feed your model with data

For instance to train a classifier all you need is a 2D array Xfor the input variables and a 1D array yfor the target
variables The array Xholds the features as columns and samples as rows The array ycontains integer values to
encode the class membership of each sample in X

128 How can I load my own datasets into a format usable by scikitlearn

Generally scikitlearn works on any numeric data stored as numpy arrays or scipy sparse matrices Other types that
are convertible to numeric arrays such as pandas DataFrame are also acceptable

For more information on loading your data files into these usable data structures please refer to loading external
datasets

129 What are the inclusion criteria for new algorithms

We only consider well-established algorithms for inclusion A rule of thumb is at least 3 years since publication 200
citations and wide use and usefulness A technique that provides a clearcut improvement eg an enhanced data
structure or a more efficient approximation technique on a widely-used method will also be considered for inclusion

From the algorithms or techniques that meet the above criteria only those which fit well within the current API (Application Programming Interface)

scikitlearn that is a fitpredicttransform interface and ordinarily having inputoutput that is a numpy array
or sparse matrix are accepted

The contributor should support the importance of the proposed addition with research papers and/or implementations
in other similar packages demonstrate its usefulness via common use-cases/applications and corroborate performance
improvements if any with benchmarks and/or plots It is expected that the proposed algorithm should outperform the
methods that are already implemented in scikitlearn at least in some areas

Inclusion of a new algorithm speeding up an existing model is easier if

- it does not introduce new hyperparameters as it makes the library more future-proof
- it is easy to document clearly when the contribution improves the speed and when it does not for instance “when
n-features n-samples”
- benchmarks clearly show a speed up

Also note that your implementation need not be in scikitlearn to be used together with scikitlearn tools You can
implement your favorite algorithm in a scikitlearn-compatible way upload it to GitHub and let us know We will be
happy to list it under Related Projects If you already have a package on GitHub following the scikitlearn API (Application Programming Interface) y
may also be interested to look at scikitlearn-contrib

1210 Why are you so selective on what algorithms you include in scikitlearn

Code is maintenance cost and we need to balance the amount of code we have with the size of the team and add to
this the fact that complexity scales non-linearly with the number of features The package relies on core developers
using their free time to fix bugs maintain code and review contributions Any algorithm that is added needs future
attention by the developers at which point the original author might long have lost interest See also What are the
inclusion criteria for new algorithms For a great read about long-term maintenance issues in open-source software
look at the Executive Summary of Roads and Bridges

4 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

1211 Why did you remove HMMs from scikitlearn

SeeWill you add graphical models or sequence prediction to scikitlearn

1212 Will you add graphical models or sequence prediction to scikitlearn

Not in the foreseeable future scikitlearn tries to provide a unified API (Application Programming Interface) for the basic tasks in machine learning w
pipelines and metaalgorithms like grid search to tie everything together The required concepts APIs algorithms
and expertise required for structured learning are different from what scikitlearn has to offer If we started doing
arbitrary structured learning we'd need to redesign the whole package and the project would likely collapse under its
own weight

There are two project with API (Application Programming Interface) similar to scikitlearn that do structured prediction

- pystruct handles general structured learning focuses on SSVMs on arbitrary graph structures with approximate inference defines the notion of sample as an instance of the graph structure
- seqlearn handles sequences only focuses on exact inference has HMMs but mostly for the sake of complete ness treats a feature vector as a sample and uses an offset encoding for the dependencies between feature vectors

1213 Will you add GPU support

No or at least not in the near future The main reason is that GPU support will introduce many software dependencies and introduce platform specific issues scikitlearn is designed to be easy to install on a wide variety of platforms Outside of neural networks GPUs don't play a large role in machine learning today and much larger gains in speed can often be achieved by a careful choice of algorithms

1214 Do you support PyPy

In case you didn't know PyPy is an alternative Python implementation with a builtin justintime compiler Experi mental support for PyPy3v510 has been added which requires Numpy 1140 and scipy 110

1215 How do I deal with string data or trees graphs

scikitlearn estimators assume you'll feed them realvalued feature vectors This assumption is hardcoded in pretty much all of the library However you can feed nonnumerical inputs to estimators in several ways

If you have text documents you can use a term frequency features see Text feature extraction for the builtin text vectorizers For more general feature extraction from any kind of data see Loading features from dicts andFeature hashing

Another common case is when you have nonnumerical data and a custom distance or similarity metric on these data Examples include strings with edit distance aka Levenshtein distance eg DNA or RNA sequences These can be encoded as numbers but doing so is painful and errorprone Working with distance metrics on arbitrary data can be done in two ways

Firstly many estimators take precomputed distancesimilarity matrices so if the dataset is not too large you can compute distances for all pairs of inputs If the dataset is large you can use feature vectors with only one "feature" which is an index into a separate data structure and supply a custom metric function that looks up the actual data in this data structure Eg to use DBSCAN with Levenshtein distances

12 Frequently Asked Questions 5

```
scikitlearn user guide Release 0213
from leven import levenshtein
import numpy as np
from sklearncluster import dbscan
data ACCTCCTAGAAG ACCTACTAGAAGTT GAATATTAGGCCGA
def levmetricx y
i j intx0 inty0 extract indices
return levenshteindatai dataj
```

```
X nparangelendatareshape1 1
X
array0
1
2
```

We need to specify algoritumbrute as the default assumes
a continuous feature space
dbscanX metriclevmetric eps5 minsamples2 algorithmbrute

```
0 1 array 0 0 1
```

This uses the thirdparty edit distance package leven
Similar tricks can be used with some care for tree kernels graph kernels etc
1216 Why do I sometime get a crashfreeze with njobs 1 under OSX or Linux
Several scikitlearn tools such as GridSearchCV andcrossvalscore rely internally on Python’s
multiprocessing module to parallelize execution onto several Python processes by passing njobs 1 as
argument

The problem is that Python multiprocessing does afork system call without following it with an exec system
call for performance reasons Many libraries like some versions of Accelerate vecLib under OSX some versions
of MKL the OpenMP runtime of GCC nvidia’s Cuda and probably many others manage their own internal thread
pool Upon a call to fork the thread pool state in the child process is corrupted the thread pool believes it has many
threads while only the main thread state has been forked It is possible to change the libraries to make them detect
when a fork happens and reinitialize the thread pool in that case we did that for OpenBLAS merged upstream in
master since 0210 and we contributed a patch to GCC’s OpenMP runtime not yet reviewed

But in the end the real culprit is Python’s multiprocessing that doesfork withoutexec to reduce the overhead
of starting and using new Python processes for parallel computing Unfortunately this is a violation of the POSIX
standard and therefore some software editors like Apple refuse to consider the lack of forksafety in Accelerate
vecLib as a bug

In Python 34 it is now possible to configure multiprocessing to use the ‘forkserver’ or ‘spawn’ start methods
instead of the default ‘fork’ to manage the process pools To work around this issue when using scikitlearn you
can set the JOBLIBSTARTMETHOD environment variable to ‘forkserver’ However the user should be aware that
using the ‘forkserver’ method prevents joblibParallel to call function interactively defined in a shell session
If you have custom code that uses multiprocessing directly instead of using it via joblib you can enable the
‘forkserver’ mode globally for your program Insert the following instructions in your main script

```
import multiprocessing
other imports custom code load data define model
ifname main
multiprocessingsetstartmethodforkserver
```

scikitlearn user guide Release 0213

call scikitlearn utils with njobs 1 here

You can find more default on the new start methods in the multiprocessing documentation

1217 Why does my job use more cores than specified with njobs under OSX or

Linux

This happens when vectorized numpy operations are handled by libraries such as MKL or OpenBLAS

While scikitlearn adheres to the limit set by njobs numpy operations vectorized using MKL or OpenBLAS will

make use of multiple threads within each scikitlearn job thread or process

The number of threads used by the BLAS library can be set via an environment variable For example to set the

maximum number of threads to some integer value N the following environment variables should be set

- For MKL export MKLNUMTHREADSN
- For OpenBLAS export OPENBLASNUMTHREADSN

1218 Why is there no support for deep or reinforcement learning Will there be

support for deep or reinforcement learning in scikitlearn

Deep learning and reinforcement learning both require a rich vocabulary to define an architecture with deep learning

additionally requiring GPUs for efficient computing However neither of these fit within the design constraints of

scikitlearn as a result deep learning and reinforcement learning are currently out of scope for what scikitlearn seeks

to achieve

You can find more information about addition of gpu support at Will you add GPU support

1219 Why is my pull request not getting any attention

The scikitlearn review process takes a significant amount of time and contributors should not be discouraged by a

lack of activity or review on their pull request We care a lot about getting things right the first time as maintenance

and later change comes at a high cost We rarely release any “experimental” code so all of our contributions will be

subject to high use immediately and should be of the highest quality possible initially

Beyond that scikitlearn is limited in its reviewing bandwidth many of the reviewers and core developers are working

on scikitlearn on their own time If a review of your pull request comes slowly it is likely because the reviewers are

busy We ask for your understanding and request that you not close your pull request or discontinue your work solely

because of this reason

1220 How do I set a randomstate for an entire execution

For testing and replicability it is often important to have the entire execution controlled by a single seed for the pseudo

random number generator used in algorithms that have a randomized component Scikitlearn does not use its own

global random state whenever a RandomState instance or an integer random seed is not provided as an argument it

relies on the numpy global random state which can be set using numpyrandomseed For example to set an

execution’s numpy global random state to 42 one could execute the following in his or her script

```
import numpy as np
```

```
np.random.seed(42)
```

12 Frequently Asked Questions 7

scikitlearn user guide Release 0213

However a global random state is prone to modification by other code during execution Thus the only way to ensure replicability is to pass RandomState instances everywhere and ensure that both estimators and crossvalidation splitters have their randomstate parameter set

1221 Why do categorical variables need preprocessing in scikitlearn compared to other tools

Most of scikitlearn assumes data is in NumPy arrays or SciPy sparse matrices of a single numeric dtype These do not explicitly represent categorical variables at present Thus unlike R's dataframes or pandasDataFrame we require explicit conversion of categorical features to numeric values as discussed in Encoding categorical features See also Column Transformer with Mixed Types for an example of working with heterogeneous eg categorical and numeric data

1222 Why does Scikitlearn not directly work with for example pandasDataFrame

The homogeneous NumPy and SciPy data objects currently expected are most efficient to process for most operations Extensive work would also be needed to support Pandas categorical types Restricting input to homogeneous types therefore reduces maintenance cost and encourages usage of efficient data structures

13 Support

There are several ways to get in touch with the developers

131 Mailing List

- The main mailing list is scikitlearn
- There is also a commit list scikitlearncommits where updates to the main repository and test failures get notified

132 User questions

- Some scikitlearn developers support users on StackOverflow using the scikitlearn tag
- For general theoretical or methodological Machine Learning questions stack exchange is probably a more suitable venue

In both cases please use a descriptive question in the title field eg no "Please help with scikitlearn" as this is not a question and put details on what you tried to achieve what were the expected results and what you observed instead in the details field

Code and data snippets are welcome Minimalistic up to 20 lines long reproduction script very helpful Please describe the nature of your data and the how you preprocessed it what is the number of samples what is the number and type of features id categorical or numerical and for supervised learning tasks what target are you trying to predict binary multiclass 1 out of nclasses or multilabel k out of nclasses classification or continuous variable regression

8 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

133 Bug tracker

If you think you’ve encountered a bug please report it to the issue tracker

<https://github.com/scikitlearn/scikitlearn/issues>

Don’t forget to include

- steps or better script to reproduce
- expected outcome
- observed outcome or python or gdb tracebacks

To help developers fix your bug faster please link to a <https://gist.github.com> holding a standalone minimalistic python script that reproduces your bug and optionally a minimalistic subsample of your dataset for instance exported as CSV files using `numpy.savetxt`

Note gists are git cloneable repositories and thus you can use git to push datafiles to them

134 IRC

Some developers like to hang out on channel `#scikitlearn` on `irc.freenode.net`

If you do not have an IRC client or are behind a firewall this web client works fine <https://webchat.freenode.net>

135 Documentation resources

This documentation is relative to 0213 Documentation for other versions can be found [here](#)

Printable pdf documentation for old versions can be found [here](#)

14 Related Projects

Projects implementing the scikitlearn estimator API (Application Programming Interface) are encouraged to use the `scikitlearncontrib` template which facilitates best practices for testing and documenting estimators The `scikitlearncontrib` GitHub organisation also

accepts highquality contributions of repositories conforming to this template

Below is a list of sisterprojects extensions and domain specific packages

141 Interoperability and framework enhancements

These tools adapt scikitlearn for use with other technologies or otherwise enhance the functionality of scikitlearn’s estimators

Data formats

- `sklearnpandas` bridge for scikitlearn pipelines and pandas data frame with dedicated transformers
- `sklearnxarray` provides compatibility of scikitlearn estimators with xarray data structures

AutoML

- `automl` Automated machine learning for production and analytics built on scikitlearn and related projects

Trains a pipeline with all the standard machine learning steps Tuned for prediction speed and ease of transfer to production environments

- `autosklearn` An automated machine learning toolkit and a dropin replacement for a scikitlearn estimator

14 Related Projects 9

scikitlearn user guide Release 0213

- TPOT An automated machine learning toolkit that optimizes a series of scikitlearn operators to design a machine learning pipeline including data and feature preprocessors as well as the estimators Works as a dropin replacement for a scikitlearn estimator
- scikitoptimize A library to minimize very expensive and noisy blackbox functions It implements several methods for sequential modelbased optimization and includes a replacement for GridSearchCV or RandomizedSearchCV to do crossvalidated parameter search using any of these strategies

Experimentation frameworks

- REP Environment for conducting datadriven research in a consistent and reproducible way
- ML Frontend provides dataset management and SVM (Support Vector Machine) fittingprediction through webbased and programmatic interfaces
- ScikitLearn Laboratory A commandline wrapper around scikitlearn that makes it easy to run machine learning experiments with multiple learners and large feature sets
- Xcessiv is a notebooklike application for quick scalable and automated hyperparameter tuning and stacked ensembling Provides a framework for keeping track of modelhyperparameter combinations

Model inspection and visualisation

- eli5 A library for debugginginspecting machine learning models and explaining their predictions
- mlxtend Includes model visualization utilities
- scikitplot A visualization library for quick and easy generation of common plots in data analysis and machine learning
- yellowbrick A suite of custom matplotlib visualizers for scikitlearn estimators to support visual feature analysis model selection evaluation and diagnostics

Model export for production

- onnxmltools Serializes many Scikitlearn pipelines to ONNX for interchange and prediction
- sklearn2pmmml Serialization of a wide variety of scikitlearn estimators and transformers into PMML with the help of JPMMLSkLearn library
- sklearnporter Transpile trained scikitlearn models to C Java Javascript and others
- sklearncompiledtrees Generate a C implementation of the predict function for decision trees and ensembles trained by sklearn Useful for latencysensitive production environments

142 Other estimators and tasks

Not everything belongs or is mature enough for the central scikitlearn project The following are projects providing interfaces similar to scikitlearn for additional learning algorithms infrastructures and tasks

Structured learning

- Seqlearn Sequence classification using HMMs or structured perceptron
- HMMLearn Implementation of hidden markov models that was previously part of scikitlearn
- PyStruct General conditional random fields and structured prediction
- pomegranate Probabilistic modelling for Python with an emphasis on hidden Markov models
- sklearncrfsuite Linearchain conditional random fields CRFsuite wrapper with sklearnlike API (Application Programming Interface)

Deep neural networks etc

- pylearn2 A deep learning and neural network library build on theano with scikitlearn like interface

10 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- sklearntheano scikitlearn compatible estimators transformers and datasets which use Theano internally
- nolearn A number of wrappers and abstractions around existing neural network libraries
- keras Deep Learning library capable of running on top of either TensorFlow or Theano
- lasagne A lightweight library to build and train neural networks in Theano
- skorch A scikitlearn compatible neural network library that wraps PyTorch

Broad scope

- mlxtend Includes a number of additional estimators as well as model visualization utilities
- sparkilearn Scikitlearn API (Application Programming Interface) and functionality for PySpark’s distributed modelling

Other regression and classification

- xgboost Optimised gradient boosted decision tree library
- MLEnsemble Generalized ensemble learning stacking blending subsemble deep ensembles etc
- lightning Fast stateoftheart linear model solvers SDCA AdaGrad SVRG SAG etc
- pyearth Multivariate adaptive regression splines
- Kernel Regression Implementation of NadarayaWatson kernel regression with automatic bandwidth selection
- gplearn Genetic Programming for symbolic regression tasks
- multiisotonic Isotonic regression on multidimensional features
- scikitmultilearn Multilabel classification with focus on label space manipulation
- seglearn Time series and sequence learning using sliding window segmentation

Decomposition and clustering

- lda Fast implementation of latent Dirichlet allocation in Cython which uses Gibbs sampling to sample from the true posterior distribution scikitlearn’s sklearndecomposition

LatentDirichletAllocation implementation uses variational inference to sample from a tractable approximation of a topic model’s posterior distribution

- Sparse Filtering Unsupervised feature learning based on sparsefiltering
- kmodes kmodes clustering algorithm for categorical data and several of its variations
- hdbscan HDBSCAN and Robust Single Linkage clustering algorithms for robust variable density clustering
- spherecluster Spherical Kmeans and mixture of von Mises Fisher clustering routines for data on the unit hyper sphere

Preprocessing

- categoricalencoding A library of sklearn compatible categorical variable encoders
- imbalancedlearn Various methods to under and oversample datasets

143 Statistical learning with Python

Other packages useful for data analysis and machine learning

- Pandas Tools for working with heterogeneous and columnar data relational queries time series and basic statistics
- theano A CPU/GPU array processing framework geared towards deep learning research

14 Related Projects 11

scikitlearn user guide Release 0213

- statsmodels Estimating and analysing statistical models More focused on statistical tests and less on prediction than scikitlearn

- PyMC Bayesian statistical models and fitting algorithms
- Sacred Tool to help you configure organize log and reproduce experiments
- Seaborn Visualization library based on matplotlib It provides a highlevel interface for drawing attractive statistical graphics

- Deep Learning A curated list of deep learning software libraries

Domain specific packages

- scikitimage Image processing and computer vision in python
- Natural language toolkit nltk Natural language processing and some machine learning
- gensim A library for topic modelling document indexing and similarity retrieval
- NiLearn Machine learning for neuroimaging
- AstroML Machine learning for astronomy
- MSMBUILDER Machine learning for protein conformational dynamics time series
- scikitsurprise A scikit for building and evaluating recommender systems

15 About us

151 History

This project was started in 2007 as a Google Summer of Code project by David Cournapeau Later that year Matthieu

Brucher started work on this project as part of his thesis

In 2010 Fabian Pedregosa Gael Varoquaux Alexandre Gramfort and Vincent Michel of INRIA took leadership of the project and made the first public release February the 1st 2010 Since then several releases have appeared following a 3 month cycle and a thriving international community has been leading the development

152 Governance

The decision making process and governance structure of scikitlearn is laid out in the governance document

153 Authors

The following people are currently core contributors to scikitlearn’s development and maintenance

Please do not email the authors directly to ask for assistance or report issues Instead please see What’s the best way to ask questions about scikitlearn in the FAQ

157 Funding

INRIA actively supports this project. It has provided funding for Fabian Pedregosa (2010-2012), Jaques Grobler (2012-2013) and Olivier Grisel (2013-2017) to work on this project fulltime. It also hosts coding sprints and other events.

Paris-Saclay Center for Data Science funded one year

for a developer to work on the project fulltime (2014-2015) and 50% of the time of Guillaume Lemaître (2016-2017).

NYU Moore-Sloan Data Science Environment funded Andreas

Mueller (2014-2016) to work on this project. The Moore-Sloan Data Science Environment also funds several students to work on the project parttime.

Télécom Paris

tech funded Manoj Kumar (2014), Tom Dupré la Tour (2015), Raghav RV (2015-2017), Thierry Guillemot (2016-2017) and Albert Thomas (2017) to work on scikitlearn.

Columbia University funds Andreas

Müller since 2016.

Andreas Müller also received a grant to improve scikitlearn from the Alfred P. Sloan Foundation in 2017.

The University of

15 About us 15

scikitlearn user guide Release 0213

Sydney funds Joel Nothman since July 2017

The Labex Digi

Cosme funded Nicolas Goix 20152016 Tom Dupré la Tour 20152016 and 20172018 Mathurin Massias 2018

2019 to work part time on scikitlearn during their PhDs It also funded a scikitlearn coding sprint in 2015

The following students were sponsored by Google to work on

scikitlearn through the Google Summer of Code program

- 2007 David Cournapeau
- 2011 Vlad Niculae
- 2012 Vlad Niculae Immanuel Bayer
- 2013 Kemal Eren Nicolas Trésegne
- 2014 Hamzeh Alsalmi Issam Laradji Maheshakya Wijewardena Manoj Kumar
- 2015 Raghav RV Wei Xue
- 2016 Nelson Liu YenChen Lin

It also provided funding for sprints and events around scikitlearn If you would like to participate in the next Google Summer of code program please see this page

The NeuroDebian project providing Debian packaging and contributions is supported by Dr James V Haxby Dartmouth College

The PSF helped find and manage funding for our 2011 Granada sprint More information can be found here

tinyclues funded the 2011 international Granada sprint

Donating to the project

If you are interested in donating to the project or to one of our codesprints you can use the Paypal button below or the

NumFOCUS Donations Page if you use the latter please indicate that you are donating for the scikitlearn project

All donations will be handled by NumFOCUS a nonprofitorganization which is managed by a board of Scipy

community members NumFOCUS's mission is to foster scientific computing software in particular in Python As

a fiscal home of scikitlearn it ensures that money is available when needed to keep the project funded and available

while in compliance with tax regulations

The received donations for the scikitlearn project mostly will go towards covering travelexpenses for code sprints as

well as towards the organization budget of the project1

1Regarding the organization budget in particular we might use some of the donated funds to pay for other project expenses such as DNS

hosting or continuous integration services

16 Chapter 1 Welcome to scikitlearn

Notes

The 2013 Paris international sprint

Fig 11 IAP VII19 DYSCO

For more information on this sprint see here

158 Infrastructure support

- We would like to thank Rackspace for providing us with a free Rackspace Cloud account to automatically build the documentation and the example gallery from for the development version of scikitlearn using this tool
- We would also like to thank Shining Panda for free CPU time on their Continuous Integration server

16 Who is using scikitlearn

161 JPMorgan

Scikitlearn is an indispensable part of the Python machine learning toolkit at JPMorgan It is very widely used across all parts of the bank for classification predictive analytics and very many other machine learning tasks Its straightforward API (Application Programming Interface) its breadth of algorithms and the quality of its documentation combine to make scikitlearn simultaneously very approachable and very powerful

Stephen Simmons VP Athena Research JPMorgan

16 Who is using scikitlearn 17

scikitlearn user guide Release 0213

162 Spotify

Scikitlearn provides a toolbox with solid implementations of a bunch of stateoftheart models and makes it easy to plug them into existing applications We’ve been using it quite a lot for music recommendations at Spotify and I think it’s the most welldesigned ML package I’ve seen so far

Erik Bernhardsson Engineering Manager Music Discovery Machine Learning Spotify

163 Inria

At INRIA we use scikitlearn to support leadingedge basic research in many teams Parietal for neuroimaging Lear for computer vision Visages for medical image analysis Privatics for security The project is a fantastic tool to address difficult applications of machine learning in an academic environment as it is performant and versatile but all easytouse and well documented which makes it well suited to grad students

Gaël Varoquaux research at Parietal

164 betaworks

Betaworks is a NYCbased startup studio that builds new products grows companies and invests in others Over the past 8 years we’ve launched a handful of social data analyticsdriven services such as Bitly Chartbeat digg and Scale Model Consistently the betaworks data science team uses Scikitlearn for a variety of tasks From exploratory analysis to product development it is an essential part of our toolkit Recent uses are included in digg’s new video recommender system and Poncho’s dynamic heuristic subspace clustering

Gilad Lotan Chief Data Scientist

18 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

165 Hugging Face

At Hugging Face we're using NLP and probabilistic models to generate conversational Artificial intelligences that are fun to chat with Despite using deep neural nets for a few of our NLP tasks scikitlearn is still the breadandbutter of our daily machine learning routine The ease of use and predictability of the interface as well as the straightforward mathematical explanations that are here when you need them is the killer feature We use a variety of scikitlearn models in production and they are also operationally very pleasant to work with

Julien Chaumond Chief Technology Officer

166 Evernote

Building a classifier is typically an iterative process of exploring the data selecting the features the attributes of the data believed to be predictive in some way training the models and finally evaluating them For many of these tasks we relied on the excellent scikitlearn package for Python

Read more

Mark Ayzenshtat VP Augmented Intelligence

167 Télécom ParisTech

At Telecom ParisTech scikitlearn is used for handson sessions and home assignments in introductory and advanced machine learning courses The classes are for undergrads and masters students The great benefit of scikitlearn is its fast learning curve that allows students to quickly start working on interesting and motivating problems

16 Who is using scikitlearn 19

scikitlearn user guide Release 0213
Alexandre Gramfort Assistant Professor
168 Bookingcom

At Bookingcom we use machine learning algorithms for many different applications such as recommending hotels and destinations to our customers detecting fraudulent reservations or scheduling our customer service agents Scikitlearn is one of the tools we use when implementing standard algorithms for prediction tasks Its API (Application Programming Interface) and its implementations are excellent and make it easy to use The scikitlearn developers do a great job of incorporating state of the art implementations and new algorithms into the package Thus scikitlearn provides convenient access to a wide spectrum of algorithms and allows us to readily find the right tool for the right job

Melanie Mueller Data Scientist
169 AWeber

The scikitlearn toolkit is indispensable for the Data Analysis and Management team at AWeber It allows us to do awesome stuff we would not otherwise have the time or resources to accomplish The documentation is excellent allowing new engineers to quickly evaluate and apply many different algorithms to our data The text feature extraction utilities are useful when working with the large volume of email content we have at AWeber The RandomizedPCA implementation along with Pipelining and FeatureUnions allows us to develop complex machine learning algorithms efficiently and reliably

Anyone interested in learning more about how AWeber deploys scikitlearn in a production environment should check out talks from PyData Boston by AWeber's Michael Becker available at <https://github.com/mdbecker/pydata2013>
Michael Becker Software Engineer Data Analysis and Management Ninjas

1610 Yhat
The combination of consistent APIs thorough documentation and top notch implementation make scikitlearn our favorite machine learning package in Python scikitlearn makes doing advanced analysis in Python accessible to anyone At Yhat we make it easy to integrate these models into your production applications Thus eliminating the unnecessary dev time encountered productionizing analytical work

Greg Lamp Cofounder Yhat
20 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

1611 Rangespan

The Python scikitlearn toolkit is a core tool in the data science group at Rangespan. Its large collection of well documented models and algorithms allow our team of data scientists to prototype fast and quickly iterate to find the right solution to our learning problems. We find that scikitlearn is not only the right tool for prototyping but its careful and well tested implementation give us the confidence to run scikitlearn models in production.

Jurgen Van Gael, Data Science Director at Rangespan Ltd

1612 Birchbox

At Birchbox we face a range of machine learning problems typical to Ecommerce: product recommendation, user clustering, inventory prediction, trends detection, etc. Scikitlearn lets us experiment with many models, especially in the exploration phase of a new project. The data can be passed around in a consistent way, models are easy to save and reuse, updates keep us informed of new developments from the pattern discovery research community. Scikitlearn is an important tool for our team, built the right way in the right language.

Thierry Bertin, Mahieux, Birchbox Data Scientist

1613 Bestofmedia Group

Scikitlearn is our 1 toolkit for all things machine learning at Bestofmedia. We use it for a variety of tasks, eg. spam fighting, ad click prediction, various ranking models, thanks to the varied state-of-the-art algorithm implementations packaged into it. In the lab, it accelerates prototyping of complex pipelines. In production, I can say it has proven to be robust and efficient enough to be deployed for business critical components.

Eustache Diemert, Lead Scientist, Bestofmedia Group

16 Who is using scikitlearn 21

scikitlearn user guide Release 0213

1614 Changeorg

At changeorg we automate the use of scikitlearn’s RandomForestClassifier in our production systems to drive email targeting that reaches millions of users across the world each week In the lab scikitlearn’s easeofuse performance and overall variety of algorithms implemented has proved invaluable in giving us a single reliable source to turn to for our machinelearning needs

Vijay Ramesh Software Engineer in Datascience at Changeorg

1615 PHIMECA Engineering

At PHIMECA Engineering we use scikitlearn estimators as surrogates for expensivetoevaluate numerical models mostly but not exclusively finiteelement mechanical models for speeding up the intensive postprocessing operations involved in our simulationbased decision making framework Scikitlearn’s fitpredict API (Application Programming Interface) together with its efficient crossvalidation tools considerably eases the task of selecting the bestfit estimator We are also using scikitlearn for illustrating concepts in our training sessions Trainees are always impressed by the easeofuse of scikitlearn despite the apparent theoretical complexity of machine learning

Vincent Dubourg PHIMECA Engineering PhD Engineer

1616 HowAboutWe

At HowAboutWe scikitlearn lets us implement a wide array of machine learning techniques in analysis and in production despite having a small team We use scikitlearn’s classification algorithms to predict user behavior enabling us to for example estimate the value of leads from a given traffic source early in the lead’s tenure on our site Also our

22 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

users’ profiles consist of primarily unstructured data answers to openended questions so we use scikitlearn’s feature extraction and dimensionality reduction tools to translate these unstructured data into inputs for our matchmaking system

Daniel Weitzenfeld Senior Data Scientist at HowAboutWe
1617 PeerIndex

At PeerIndex we use scientific methodology to build the Influence Graph a unique dataset that allows us to identify who’s really influential and in which context To do this we have to tackle a range of machine learning and predictive modeling problems Scikitlearn has emerged as our primary tool for developing prototypes and making quick progress From predicting missing data and classifying tweets to clustering communities of social media users scikitlearn proved useful in a variety of applications Its very intuitive interface and excellent compatibility with other python tools makes it an indispensable tool in our daily research efforts

Ferenc Huszar Senior Data Scientist at Peerindex
1618 DataRobot

DataRobot is building next generation predictive analytics software to make data scientists more productive and scikitlearn is an integral part of our system The variety of machine learning techniques in combination with the solid implementations that scikitlearn offers makes it a onestopshopping library for machine learning in Python Moreover its consistent API (Application Programming Interface) welltested code and permissive licensing allow us to use it in a production environment Scikitlearn has literally saved us years of work we would have had to do ourselves to bring our product to market

Jeremy Achin CEO Cofounder DataRobot Inc

1619 OkCupid

We’re using scikitlearn at OkCupid to evaluate and improve our matchmaking system The range of features it has especially preprocessing utilities means we can use it for a wide variety of projects and it’s performant enough to handle the volume of data that we need to sort through The documentation is really thorough as well which makes the library quite easy to use

David Koh Senior Data Scientist at OkCupid

16 Who is using scikitlearn 23

scikitlearn user guide Release 0213

1620 Lovely

At Lovely we strive to deliver the best apartment marketplace with respect to our users and our listings From understanding user behavior improving data quality and detecting fraud scikitlearn is a regular tool for gathering insights predictive modeling and improving our product The easytoread documentation and intuitive architecture of the API (Application Programming Interface) makes machine learning both explorable and accessible to a wide range of python developers I’m con recommending that more developers and scientists try scikitlearn

Simon Frid Data Scientist Lead at Lovely

1621 Data Publica

Data Publica builds a new predictive sales tool for commercial and marketing teams called CRadar We extensively use scikitlearn to build segmentations of customers through clustering and to predict future customers based on past partnerships success or failure We also categorize companies using their website communication thanks to scikitlearn and its machine learning algorithm implementations Eventually machine learning makes it possible to detect weak signals that traditional tools cannot see All these complex tasks are performed in an easy and straightforward way thanks to the great quality of the scikitlearn framework

Guillaume Lebourgeois Samuel Charron Data Scientists at Data Publica

1622 Machinalis

Scikitlearn is the cornerstone of all the machine learning projects carried at Machinalis It has a consistent API (Application Programming Interface) wide selection of algorithms and lots of auxiliary tools to deal with the boilerplate We have used it in production environments on a variety of projects including clickthrough rate prediction information extraction and even counting sheep

In fact we use it so much that we’ve started to freeze our common use cases into Python packages some of them opensourced like FeatureForge Scikitlearn in one word Awesome

Rafael Carrascosa Lead developer

24 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

1623 solido

Scikitlearn is helping to drive Moore’s Law via Solido Solido creates computeraided design tools used by the majority of top20 semiconductor companies and fabs to design the bleedingedge chips inside smartphones auto mobiles and more Scikitlearn helps to power Solido’s algorithms for rareevent estimation worstcase verification optimization and more At Solido we are particularly fond of scikitlearn’s libraries for Gaussian Process models largescale regularized linear regression and classification Scikitlearn has increased our productivity because for many ML problems we no longer need to “roll our own” code This PyData 2014 talk has details

Trent McConaghy founder Solido Design Automation Inc

1624 INFONEA

We employ scikitlearn for rapid prototyping and custommade Data Science solutions within our inmemory based Business Intelligence Software INFONEA® As a welldocumented and comprehensive collection of stateoftheart algorithms and pipelining methods scikitlearn enables us to provide flexible and scalable scientific analysis solutions Thus scikitlearn is immensely valuable in realizing a powerful integration of Data Science technology within self service business analytics

Thorsten Kranz Data Scientist Coma Soft AG

1625 Dataiku

Our software Data Science Studio DSS enables users to create data services that combine ETL with Machine Learning Our Machine Learning module integrates many scikitlearn algorithms The scikitlearn library is a perfect integration with DSS because it offers algorithms for virtually all business cases Our goal is to offer a transparent and flexible tool that makes it easier to optimize time consuming aspects of building a data service preparing data and training machine learning algorithms on all types of data

Florian Douetteau CEO Dataiku

1626 Otto Group

Here at Otto Group one of global Big Five B2C online retailers we are using scikitlearn in all aspects of our daily work from data exploration to development of machine learning application to the productive deployment of those services It helps us to tackle machine learning problems ranging from ecommerce to logistics It consistent APIs enabled us to build the Palladium RESTAPI framework around it and continuously deliver scikitlearn based services

16 Who is using scikitlearn 25

scikitlearn user guide Release 0213

Christian Rammig Head of Data Science Otto Group

1627 Zopa

At Zopa the first ever PeertoPeer lending platform we extensively use scikitlearn to run the business and optimize our users’ experience It powers our Machine Learning models involved in credit risk fraud risk marketing and pricing and has been used for originating at least 1 billion GBP worth of Zopa loans It is very well documented powerful and simple to use We are grateful for the capabilities it has provided and for allowing us to deliver on our mission of making money simple and fair

Vlasios Vasileiou Head of Data Science Zopa

1628 MARS

ScikitLearn is integral to the Machine Learning Ecosystem at Mars Whether we’re designing better recipes for petfood or closely analysing our cocoa supply chain ScikitLearn is used as a tool for rapidly prototyping ideas and taking them to production This allows us to better understand and meet the needs of our consumers worldwide ScikitLearn’s featurerich toolset is easy to use and equips our associates with the capabilities they need to solve the business challenges they face every day

Michael Fitzke Next Generation Technologies Sr Leader Mars Inc

17 Release History

Release notes for current and recent releases are detailed on this page with previous releases linked below

Tip Subscribe to scikitlearn releases on librariesio to be notified when new versions are released

171 Legend for changelogs

- MAJOR FEATURE something big that you couldn’t do before
- FEATURE something that you couldn’t do before
- EFFICIENCY an existing feature now may not require as much computation or memory
- ENHANCEMENT a miscellaneous minor improvement
- FIX something that previously didn’t work as documented – or according to reasonable expectations – should now work
- API (Application Programming Interface) C HANGE you will need to change your code to have the same effect in the future or a feature will be removed in the future

26 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

18 Version 0213

July 30 2019

181 Changed models

The following estimators and functions when fit with the same data and parameters may produce different models from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in random sampling procedures

- The v0200 release notes failed to mention a backwards incompatibility in metricsmakescorer whenneedsprobaTrue andytrue is binary Now the scorer function is supposed to accept a 1D ypred ie probability of the positive class shape nsamples instead of a 2D ypred ie shape nsamples 2

182 Changelog

sklearncluster

- FIXFixed a bug in clusterKMeans where computation with initrandom was single threaded for njobs 1 ornjobs 1 12955 by Prabakaran Kumaresshan
- FIXFixed a bug in clusterOPTICS where users were unable to pass float minsamples and minclustersize 14496 by Fabian Klopfer and Hanmin Qin

sklearncompose

- FIXFixed an issue in composeColumnTransformer where using DataFrames whose column order differs between func fit and functransform could lead to silently passing incorrect columns to the remainder transformer 14237 by Andreas Schuderer

sklearndatasets

- FIXdatasetsfetchcaliforniahousing datasetsfetchcovtype datasets fetchkddcup99 datasetsfetcholivettifaces datasetsfetchrcv1 and datasetsfetchspeciesdistributions try to persist the previously cache using the new joblib if the cached data was persisted using the deprecated sklearnexternalsjoblib This behavior is set to be deprecated and removed in v023 14197 by Adrin Jalali

sklearnensemble

- FIX Fix zero division error in HistGradientBoostingClassifier and HistGradientBoostingRegressor 14024 by Nicolas Hug

sklearnimpute

- FIXFixed a bug in imputeSimpleImputer andimputeliterativeImputer so that no errors are thrown when there are missing values in training data 13974 by Frank Hoang

18 Version 0213 27

scikitlearn user guide Release 0213

sklearninspection

- FIXFixed a bug in inspectionplotpartialdependence wheretarget parameter was not being taken into account for multiclass problems 14393 by Guillem G Subies

sklearnlinearmodel

- FIXFixed a bug in linearmodelLogisticRegressionCV whererefitFalse would fail depending on the multiclass andpenalty parameters regression introduced in 021 14087 by Nicolas Hug
- FIXCompatibility fix for linearmodelARDRegression and Scipy130 Adapts to upstream changes to the default pinvh cutoff threshold which otherwise results in poor accuracy in some cases 14067 by Tim Staley

sklearnneighbors

- FIXFixed a bug in neighborsNeighborhoodComponentsAnalysis where the validation of initial parameters ncomponents maxiter andtol required too strict types 14092 by Jérémie du Boisber

sklearnranger

- FIXFixed bug in treeexporttext when the tree has one feature and a single feature name is passed in 14053 by Thomas Fan
- FIXFixed an issue with plottree where it displayed entropy calculations even for gini criterion in DecisionTreeClassifiers 13947 by Frank Hoang

19 Version 0212

24 May 2019

191 Changelog

sklearndecomposition

- FIXFixed a bug in crossdecompositionCCA improving numerical stability when Yis close to zero 13903 by Thomas Fan

sklearnmetrics

- FIXFixed a bug in metricspairwiseeuclideananddistances where a part of the distance matrix was left uninstantiated for sufficiently large float32 datasets regression introduced in 021 13910 by Jérémie du Boisberranger

28 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

sklearnpreprocessing

•FIXFixed a bug in preprocessingOneHotEncoder where the new drop parameter was not reflected

in getfeaturenames 13894 by James Myatt

sklearnutilssparsefuncs

•FIXFixed a bug where minmaxaxis would fail on 32bit systems for certain large inputs This

affects preprocessingMaxAbsScaler preprocessingnormalize and preprocessing

LabelBinarizer 13741 by Roddy MacSween

110 Version 0211

17 May 2019

This is a bugfix release to primarily resolve some packaging issues in version 0210 It also includes minor docu

mentation improvements and some bug fixes

1101 Changelog

sklearninspection

•FIXFixed a bug in inspectionpartialdependence to only check classifier and not regressor for

the multiclassmultioutput case 14309 by Guillaume Lemaitre

sklearnmetrics

•FIXFixed a bug in metricspairwiselocaldistances where it would raise AttributeError for

boolean metrics when X had a boolean dtype and Y None 13864 by Paresh Mathur

•FIXFixed two bugs in metricspairwiselocaldistances when njobs 1 First it used to return a

distance matrix with same dtype as input even for integer dtype Then the diagonal was not zeros for euclidean

metric when Y is X 13877 by Jérémie du Boisberranger

sklearnneighbors

•FIXFixed a bug in neighborsKernelDensity which could not be restored from a pickle if

sampleweight had been used 13772 by Aditya Vyas

111 Version 0210

May 2019

110 Version 0211 29

scikitlearn user guide Release 0213

1111 Changed models

The following estimators and functions when fit with the same data and parameters may produce different models from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in random sampling procedures

- discriminantanalysisLinearDiscriminantAnalysis for multiclass classification FIX
- discriminantanalysisLinearDiscriminantAnalysis with ‘eigen’ solver FIX
- linearmodelBayesianRidge FIX
- Decision trees and derived ensembles when both maxdepth andmaxleafnodes are set FIX
- linearmodelLogisticRegression andlinearmodelLogisticRegressionCV with ‘saga’ solver FIX
- ensembleGradientBoostingClassifier FIX
- sklearnfeatureextractiontextHashingVectorizer sklearnfeatureextractiontextTfidfVectorizer and sklearnfeatureextractiontextCountVectorizer FIX
- neuralnetworkMLPClassifier FIX
- svmSVCdecisionfunction and multiclassOneVsOneClassifier decisionfunction FIX
- linearmodelSGDClassifier and any derived classifiers FIX
- Any model using the linearmodelsagsagsolver function with a 0seed includ inglinearmodelLogisticRegression linearmodelLogisticRegressionCV linearmodelRidge andlinearmodelRidgeCV with ‘sag’ solver FIX
- linearmodelRidgeCV when using generalized crossvalidation with sparse inputs FIX

Details are listed in the changelog below

While we are trying to better inform users by providing this information we cannot assure that this list is complete

1112 Known Major Bugs

- The default maxiter forlinearmodelLogisticRegression is too small for many solvers given the defaulttol In particular we accidentally changed the default maxiter for the liblinear solver from 1000 to 100 iterations in 3591 released in version 016 In a future release we hope to choose better default maxiter andtol heuristically depending on the solver see 13317

1113 Changelog

Support for Python 34 and below has been officially dropped

sklearnbase

- API (Application Programming Interface) C HANGE The R2 score used when calling score on a regressor will use multioutputuniformaverage from version 023 to keep consistent with metricsr2score This will influence the score method of all the multioutput regressors except for multioutput

MultiOutputRegressor 13157 by Hanmin Qin

30 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

sklearncalibration

- ENHANCEMENT Added support to bin the data passed into calibrationcalibrationcurve by quantiles instead of uniformly between 0 and 1 13086 by Scott Cole

- ENHANCEMENT Allow ndimensional arrays as input for calibrationCalibratedClassifierCV 13485 by William de Vazelhes

sklearncluster

- MAJOR FEATURE A new clustering algorithm clusterOPTICS an algorithm related to cluster DBSCAN that has hyperparameters easier to set and that scales better by Shane Adrin Jalali Erich Schubert Hanmin Qin and Assia Benbihi

- FIXFixed a bug where clusterBirch could occasionally raise an AttributeError 13651 by Joel Nothman

- FIXFixed a bug in clusterKMeans where empty clusters weren't correctly relocated when using sample weights 13486 by Jérémie du Boisberranger

- API (Application Programming Interface) C HANGE Thencomponents attribute in clusterAgglomerativeClustering and clusterFeatureAgglomeration has been renamed to nconnectedcomponents 13427 by Stephane Couvreur

- ENHANCEMENT clusterAgglomerativeClustering andclusterFeatureAgglomeration now accept a distancethreshold parameter which can be used to find the clusters instead of nclusters 9069 by Vathsala Achar and Adrin Jalali

sklearncompose

- API (Application Programming Interface) C HANGE composeColumnTransformer is no longer an experimental feature 13835 by Hanmin Qin

sklearnndatasets

- FIXAdded support for 64bit group IDs and pointers in SVMLight files 10727 by Bryan K Woods

- FIXdatasetsloadsampleimages returns images with a deterministic order 13250 by Thomas Fan

sklearnndecomposition

- ENHANCEMENT decompositionKernelPCA now has deterministic output resolved sign ambiguity in eigenvalue decomposition of the kernel matrix 13241 by Aurélien Bellet

- FIXFixed a bug in decompositionKernelPCA fittransform now produces the correct output the same as fittransform in case of nonremoved zero eigenvalues removezeroeigFalse fitinversetransform was also accelerated by using the same trick asfittransform to compute the transform of X 12143 by Sylvain Marié

- FIXFixed a bug in decompositionNMF whereinit_nndsvd init_nndsvda and init_nndsvdar are allowed when ncomponents_nfeatures instead ofncomponents_minnsamples_nfeatures 11650 by Hossein Pourbozorg and Zijie ZJ Poh

scikitlearn user guide Release 0213

•API (Application Programming Interface) C HANGE The default value of the init argument in decomposition nonnegativefactorization will change from random toNone in version 023 to make it consistent with decompositionNMF A FutureWarning is raised when the default value is used 12988

by Zijie ZJ Poh

sklearnndiscriminantanalysis

•ENHANCEMENT discriminantanalysisLinearDiscriminantAnalysis now preserves float32 andfloat64 dtypes 8769 and 11000 by Thibault Sejourne

•FIXAChangedBehaviourWarning is now raised when discriminantanalysis

LinearDiscriminantAnalysis is given as parameter ncomponents minnfeatures

nclasses 1 andncomponents is changed to minnfeatures nclasses 1 if so

Previously the change was made but silently 11526 by William de Vazelhes

•FIXFixed a bug in discriminantanalysisLinearDiscriminantAnalysis where the pre

dicted probabilities would be incorrectly computed in the multiclass case 6848 by Agamemnon Krasoulis

andGuillaume Lemaitre

•FIXFixed a bug in discriminantanalysisLinearDiscriminantAnalysis where the pre

dicted probabilities would be incorrectly computed with eigen solver 11727 by Agamemnon Krasoulis

sklearndummy

•FIXFixed a bug in dummyDummyClassifier where thepredictproba method was returning int32

array instead of float64 for the stratified strategy 13266 by Christos Aridas

•FIXFixed a bug in dummyDummyClassifier where it was throwing a dimension mismatch error in

prediction time if a column vector ywithshapen 1 was given at fit time 13545 by Nick Sorros and

Adrin Jalali

sklearnensemble

•MAJOR FEATURE Add two new implementations of gradient boosting trees ensemble

HistGradientBoostingClassifier andensembleHistGradientBoostingRegressor

The implementation of these estimators is inspired by LightGBM and can be orders of magnitude faster than

ensembleGradientBoostingRegressor andensembleGradientBoostingClassifier

when the number of samples is larger than tens of thousands of samples The API (Application Programming Interface) of these new estimators

is slightly different and some of the features from ensembleGradientBoostingClassifier and

ensembleGradientBoostingRegressor are not yet supported

These new estimators are experimental which means that their results or their API (Application Programming Interface) might change without any

deprecation cycle To use them you need to explicitly import enablehistgradientboosting

explicitly require this experimental feature

from sklearnexperimental import enablehistgradientboosting noqa

now you can import normally from sklearnensemble

from sklearnensemble import HistGradientBoostingClassifier

12807 by Nicolas Hug

•FEATURE AddensembleVotingRegressor which provides an equivalent of ensemble

VotingClassifier for regression problems 12513 by Ramil Nugmanov and Mohamed Ali Jamaoui

32 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- EFFICIENCY MakeensembleIsolationForest prefer threads over processes when running with njobs 1 as the underlying decision tree fit calls do release the GIL This changes reduces memory usage and communication overhead 12543 by Isaac Storch and Olivier Grisel
- EFFICIENCY MakeensembleIsolationForest more memory efficient by avoiding keeping in memory each tree prediction 13260 by Nicolas Goix
- EFFICIENCY ensembleIsolationForest now uses chunks of data at prediction step thus capping the memory usage 13283 by Nicolas Goix
- EFFICIENCY sklearnensembleGradientBoostingClassifier andsklearnensemble GradientBoostingRegressor now keep the input yasfloat64 to avoid it being copied internally by trees 13524 by Adrin Jalali
- ENHANCEMENT Minimized the validation of X in ensembleAdaBoostClassifier andensemble AdaBoostRegressor 13174 by Christos Aridas
- ENHANCEMENT ensembleIsolationForest now exposes warmstart parameter allowing iterative addition of trees to an isolation forest 13496 by Peter Marko
- FIXThe values of featureimportances in all random forest based models ie ensembleRandomForestClassifier ensembleRandomForestRegressor ensembleExtraTreesClassifier ensembleExtraTreesRegressor ensemble RandomTreesEmbedding ensembleGradientBoostingClassifier andensemble GradientBoostingRegressor now -sum up to1 -all the single node trees in feature importance calculation are ignored -in case all trees have only one single node ie a root node feature importances will be an array of all zeros 13636 and 13620 by Adrin Jalali
- FIXFixed a bug in ensembleGradientBoostingClassifier andensemble GradientBoostingRegressor which didn't support scikitlearn estimators as the initial estimator Also added support of initial estimator which does not support sample weights 12436 by Jérémie du Boisberranger and 12983 by Nicolas Hug
- FIXFixed the output of the average path length computed in ensembleIsolationForest when the input is either 0 1 or 2 13251 by Albert Thomas and joshuakennethjones
- FIXFixed a bug in ensembleGradientBoostingClassifier where the gradients would be incor rectly computed in multiclass classification problems 12715 by Nicolas Hug
- FIXFixed a bug in ensembleGradientBoostingClassifier where validation sets for early stop ping were not sampled with stratification 13164 by Nicolas Hug
- FIXFixed a bug in ensembleGradientBoostingClassifier where the default initial prediction of a multiclass classifier would predict the classes priors instead of the log of the priors 12983 by Nicolas Hug
- FIXFixed a bug in ensembleRandomForestClassifier where thepredict method would error for multiclass multioutput forests models if any targets were strings 12834 by Elizabeth Sander
- FIXFixed a bug in ensemblegradientboostingLossFunction andensemble gradientboostingLeastSquaresError where the default value of learningrate in updateterminalregions is not consistent with the document and the caller functions Note however that directly using these loss functions is deprecated 6463 by movelikeriver
- FIXensemblepartialdependence and consequently the new version sklearninspection partialdependence now takes sample weights into account for the partial dependence computation when the gradient boosting model has been trained with sample weights 13193 by Samuel O Ronsin

scikitlearn user guide Release 0213

- API (Application Programming Interface) C HANGE ensemblepartialdependence andensembleplotpartialdependence are now deprecated in favor of inspectionpartialdependence andinspection plotpartialdependence 12599 by Trevor Stephens and Nicolas Hug
- FIXensembleVotingClassifier andensembleVotingRegressor were failing during fit in one of the estimators was set to None andsampleweight was notNone 13779 by Guillaume Lemaitre
- API (Application Programming Interface) C HANGE ensembleVotingClassifier andensembleVotingRegressor acceptdrop to disable an estimator in addition to None to be consistent with other estimators ie pipeline FeatureUnion andcomposeColumnTransformer 13780 by Guillaume Lemaitre

sklearnexternals

- API (Application Programming Interface) C HANGE Deprecated externalssix since we have dropped support for Python 27 12916 by Han min Qin

sklearnfeatureextraction

- FIXIfinputfile orinputfilename and a callable is given as the analyzer sklearn featureextractiontextHashingVectorizer sklearnfeatureextractiontext TfidfVectorizer andsklearnfeatureextractiontextCountVectorizer now read the data from the files and then pass it to the given analyzer instead of passing the file names or the file objects to the analyzer 13641 by Adrin Jalali

sklearnimpute

- MAJOR FEATURE AddedimputeIterativeImputer which is a strategy for imputing missing values by modeling each feature with missing values as a function of other features in a roundrobin fashion 8478 and 12177 by Sergey Feldman and Ben Lawson

The API (Application Programming Interface) of IterativeImputer is experimental and subject to change without any deprecation cycle To use them you need to explicitly import enableiterativeimputer

from sklearnexperimental import enableiterativeimputer noqa

now you can import normally from sklearnimpute

from sklearnimpute import IterativeImputer

- FEATURE TheimputeSimpleImputer andimputeIterativeImputer have a new parameter addindicator which simply stacks a imputeMissingIndicator transform into the output of the imputer's transform That allows a predictive estimator to account for missingness 12583 13601 by Danylo Baibak

- FIXInimputeMissingIndicator avoid implicit densification by raising an exception if input is sparse addmissingvalues property is set to 0 13240 by Bartosz Telenczuk

- FIXFixed two bugs in imputeMissingIndicator First when Xis sparse all the nonzero non missing values used to become explicit False in the transformed data Then when featuresmissingonly all features used to be kept if there were no missing values at all 13562 by Jérémie du Boisberranger

sklearninspection

new subpackage

34 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- FEATURE Partial dependence plots inspectionplotpartialdependence are now supported for any regressor or classifier provided that they have a predictproba method 12599 by Trevor Stephens and Nicolas Hug

sklearnisotonic

- FEATURE Allow different dtypes such as float32 in isotoniclsotonicRegression 8769 by Vlad Niculae

sklearnlinearmodel

- ENHANCEMENT linearmodelRidge now preserves float32 andfloat64 dtypes 8769 and 11000 by Guillaume Lemaitre and Joan Massich

- FEATURE linearmodelLogisticRegression and linearmodel

LogisticRegressionCV now support ElasticNet penalty with the ‘saga’ solver 11646 by Nicolas Hug

- FEATURE Addedlinearmodellarspathgram which is linearmodellarspath in the sufficient stats mode allowing users to compute linearmodellarspath without providing Xandy 11699 by Kuai Yu

- EFFICIENCY linearmodelmakedataset now preserves float32 andfloat64 dtypes reducing memory consumption in stochastic gradient SAG and SAGA solvers 8769 and 11000 by Nelle Varoquaux Arthur Imbert Guillaume Lemaitre and Joan Massich

- ENHANCEMENT linearmodelLogisticRegression now supports an unregularized objective when penaltynone is passed This is equivalent to setting Cnpinf with l2 regularization Not supported by the liblinear solver 12860 by Nicolas Hug

- ENHANCEMENT sparsecg solver inlinearmodelRidge now supports fitting the intercept ie fitinterceptTrue when inputs are sparse 13336 by Bartosz Telenczuk

- ENHANCEMENT The coordinate descent solver used in Lasso ElasticNet etc now issues a ConvergenceWarning when it completes without meeting the desired toleranbce 11754 and 13397 by Brent Fagan and Adrin Jalali

- FIXFixed a bug in linearmodelLogisticRegression andlinearmodel LogisticRegressionCV with ‘saga’ solver where the weights would not be correctly updated in some cases 11646 by Tom Dupre la Tour

- FIXFixed the posterior mean posterior covariance and returned regularization parameters in linearmodelBayesianRidge The posterior mean and the posterior covariance were not the ones computed with the last update of the regularization parameters and the returned regularization parameters were not the final ones Also fixed the formula of the log marginal likelihood used to compute the score when computescoreTrue 12174 by Albert Thomas

- FIXFixed a bug in linearmodelLassoLarsIC where user input copyXFalse at instance creation would be overridden by default parameter value copyXTrue in fit 12972 by Lucio Fernandez Arjona

- FIXFixed a bug in linearmodelLinearRegression that was not returning the same coefficients and intercepts with fitinterceptTrue in sparse and dense case 13279 by Alexandre Gramfort

- FIXFixed a bug in linearmodelHuberRegressor that was broken when Xwas of dtype bool 13328 by Alexandre Gramfort

111 Version 0210 35

scikitlearn user guide Release 0213

- FIXFixed a performance issue of saga andsag solvers when called in a joblibParallel setting with njobs 1 andbackendthreading causing them to perform worse than in the sequential case 13389 by Pierre Glaser
 - FIXFixed a bug in linearmodelstochasticgradientBaseSGDClassifier that was not deterministic when trained in a multiclass setting on several threads 13422 by Clément Doumouro
 - FIX Fixed bug in linearmodelridgeregression linearmodelRidge andlinearmodelRidgeClassifier that caused unhandled exception for arguments returninterceptTrue andsolverauto default or any other solver different from sag 13363 by Bartosz Telenczuk
 - FIXlinearmodelridgeregression will now raise an exception if returninterceptTrue and solver is different from sag Previously only warning was issued 13363 by Bartosz Telenczuk
 - FIXlinearmodelridgeregression will choose sparsecg solver for sparse inputs when solverauto andsampleweight is provided previously cholesky solver was selected 13363 by Bartosz Telenczuk
 - API (Application Programming Interface) C HANGE The use oflinearmodelarspath withXNone while passing Gram is deprecated in version 021 and will be removed in version 023 Use linearmodelarspathgram instead 11699 by Kuai Yu
 - API (Application Programming Interface) C HANGE linearmodellogisticregressionpath is deprecated in version 021 and will be removed in version 023 12821 by Nicolas Hug
 - FIXlinearmodelRidgeCV with generalized crossvalidation now correctly fits an intercept when fitinterceptTrue and the design matrix is sparse 13350 by Jérôme Dockès
 - sklearnmanifold
 - EFFICIENCY Makemanifoldtsnetrustworthiness use an inverted index instead of an npwhere lookup to find the rank of neighbors in the input space This improves efficiency in particular when computed with lots of neighbors andor small datasets 9907 by William de Vazelhes
 - sklearnmetrics
 - FEATURE Added themetricsmaxerror metric and a corresponding maxerror scorer for single output regression 12232 by Krishna Sangeeth
 - FEATURE Addmetricsmultilabelconfusionmatrix which calculates a confusion matrix with true positive false positive false negative and true negative counts for each class This facilitates the calculation of setwise metrics such as recall specificity fall out and miss rate 11179 by Shangwu Yao and Joel Nothman
 - FEATURE metricsjaccardscore has been added to calculate the Jaccard coefficient as an evaluation metric for binary multilabel and multiclass tasks with an interface analogous to metricsf1score 13151 by Gaurav Dhingra and Joel Nothman
 - FEATURE Addedmetricspairwiseaversinedistances which can be accessed with metricpairwise throughmetricspairwisedistances and estimators Haversine distance was previously available for nearest neighbors calculation 12568 by Wei Xue Emmanuel Arias and Joel Nothman
 - EFFICIENCY Fastermetricspairwisedistances with njobs 1 by using a threadbased backend instead of processbased backends 8216 by Pierre Glaser and Romuald Menuet
 - EFFICIENCY The pairwise manhattan distances with sparse input now uses the BLAS shipped with scipy instead of the bundled BLAS 12732 by Jérémie du Boisberranger
- 36 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- ENHANCEMENT Use label accuracy instead of microaverage onmetrics classificationreport to avoid confusion microaverage is only shown for multilabel or multiclass with a subset of classes because it is otherwise identical to accuracy 12334 by Emmanuel Arias Joel Nothman and Andreas Müller
 - ENHANCEMENT Addedbeta parameter to metricshomogeneitycompletenessvmeasure and metricsvmeasurescore to configure the tradeoff between homogeneity and completeness 13607 by Stephane Couvreur and Ivan Sanchez
 - FIXThe metric metricsr2score is degenerate with a single sample and now it returns NaN and raises exceptionsUndefinedMetricWarning 12855 by Pawel Sendyk
 - FIXFixed a bug where metricsbrierscoreloss will sometimes return incorrect result when there's only one class in ytrue 13628 by Hanmin Qin
 - FIXFixed a bug in metricslabelrankingaverageprecisionscore where sampleweight wasn't taken into account for samples with degenerate labels 13447 by Dan Ellis
 - API (Application Programming Interface) C HANGE The parameter labels inmetricshammingloss is deprecated in version 021 and will be removed in version 023 10580 by Reshama Shaikh and Sandra Mitrovic
 - FIXThe function metricspairwiseeuclidean distances and therefore several estimators with metricceclidean suffered from numerical precision issues with float32 features Precision has been increased at the cost of a small drop of performance 13554 by Celelibi and Jérémie du Boisberranger
 - API (Application Programming Interface) C HANGE metricsjaccardsimilarityscore is deprecated in favour of the more consistent metricsjaccardscore The former behavior for binary and multiclass targets is broken 13151 by Joel Nothman
- sklearnmixture
- FIXFixed a bug in mixtureBaseMixture and therefore on estimators based on it ie mixture GaussianMixture andmixtureBayesianGaussianMixture whererefitpredict andfit predict were not equivalent 13142 by Jérémie du Boisberranger
- sklearnmodelselection
- FEATURE ClassesGridSearchCV andRandomizedSearchCV now allow for refitcallable to add flexibility in identifying the best estimator See Balance model complexity and crossvalidated score 11354 by Wenhao Zhang Joel Nothman and Adrin Jalali
 - ENHANCEMENT ClassesGridSearchCV RandomizedSearchCV and methods crossvalscore crossvalpredict crossvalidate now print train scores when returntrainscores is True and verbose 2 Forlearningcurve andvalidationcurve only the latter is required 12613 and 12669 by Marc Torrellas
 - ENHANCEMENT Some CV (Cross-Validation) splitter classes and modelselectiontraintestsplit now raise ValueError when the resulting training set is empty 12861 by Nicolas Hug
 - FIXFixed a bug where modelselectionStratifiedKFold shuffles each class's samples with the samerandomstate makingshuffleTrue ineffective 13124 by Hanmin Qin
 - FIXAdded ability for modelselectioncrossvalpredict to handle multilabel and multioutputmulticlass targets with predictproba type methods 8773 by Stephen Hoover
 - FIXFixed an issue in crossvalpredict wheremethodpredictproba returned always 00 when one of the classes was excluded in a crossvalidation fold 13366 by Guillaume Fournier
- 111 Version 0210 37

scikitlearn user guide Release 0213

sklearnmulticlass

- FIXFixed an issue in multiclassOneVsOneClassifierdecisionfunction where the decisionfunction value of a given sample was different depending on whether the decisionfunction was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decisionfunction 10440 by Jonathan Ohayon

sklearnmultioutput

- FIXFixed a bug in multioutputMultiOutputClassifier where the predictproba method incorrectly checked for predictproba attribute in the estimator object 12222 by Rebekah Kim

sklearnneighbors

- MAJOR FEATURE AddedneighborsNeighborhoodComponentsAnalysis for metric learning which implements the Neighborhood Components Analysis algorithm 10058 by William de Vazelhes and John Chiotellis
- API (Application Programming Interface) C HANGE Methods in neighborsNearestNeighbors kneighbors radiusneighbors kneighborsgraph radiusneighborsgraph now raise NotFittedError rather than AttributeError when called before fit 12279 by Krishna Sangeeth

sklearnneuralnetwork

- FIXFixed a bug in neuralnetworkMLPClassifier andneuralnetworkMLPRegressor where the option shuffleFalse was being ignored 12582 by Sam Waterbury
- FIXFixed a bug in neuralnetworkMLPClassifier where validation sets for early stopping were not sampled with stratification In the multilabel case however splits are still not stratified 13164 by Nicolas Hug

sklearnpipeline

- FEATURE pipelinePipeline can now use indexing notation eg mypipeline01 to extract a subsequence of steps as another Pipeline instance A Pipeline can also be indexed directly to extract a particular step egmypipelinesvc rather than accessing namedsteps 2568 by Joel Nothman
- FEATURE Added optional parameter verbose inpipelinePipeline compose ColumnTransformer andpipelineFeatureUnion and corresponding make helpers for showing progress and timing of each step 11364 by Baze Petrushev Karan Desai Joel Nothman and Thomas Fan
- ENHANCEMENT pipelinePipeline now supports using passthrough as a transformer with the same effect as None 11144 by Thomas Fan
- ENHANCEMENT pipelinePipeline implements len and therefore lenpipeline returns the number of steps in the pipeline 13439 by Lakshya KD

sklearnpreprocessing

- FEATURE preprocessingOneHotEncoder now supports dropping one feature per category with a new drop parameter 12908 by Drew Johnston
- EFFICIENCY preprocessingOneHotEncoder andpreprocessingOrdinalEncoder now handle pandas DataFrames more efficiently 13253 by maikia

scikitlearn user guide Release 0213

- EFFICIENCY MakepreprocessingMultiLabelBinarizer cache class mappings instead of calculating it every time on the fly 12116 by Ekaterina Krivich and Joel Nothman
 - EFFICIENCY preprocessingPolynomialFeatures now supports compressed sparse row CSR (Compressed Sparse Row) matrices as input for degrees 2 and 3 This is typically much faster than the dense case as it scales with matrix density and expansion degree on the order of densitydegree and is much much faster than the compressed sparse column CSC case 12197 by Andrew Nystrom
 - EFFICIENCY Speed improvement in preprocessingPolynomialFeatures in the dense case Also added a new parameter order which controls output order for further speed performances 12251 by Tom Dupre la Tour
 - FIXFixed the calculation overflow when using a float16 dtype with preprocessingStandardScaler 13007 by Raffaello Baluyot
 - FIXFixed a bug in preprocessingQuantileTransformer andpreprocessingquantiletransform to force nquantiles to be at most equal to nsamples Values of nquantiles larger than nsamples were either useless or resulting in a wrong approximation of the cumulative distribution function estimator 13333 by Albert Thomas
 - API (Application Programming Interface) C HANGE The default value of copy inpreprocessingquantiletransform will change from False to True in 023 in order to make it more consistent with the default copy values of other functions in preprocessing and prevent unexpected side effects by modifying the value of Xinplace 13459 by Hunter McGushion
- sklearnsvm
- FIXFixed an issue in svmSVCdecisionfunction whendecisionfunctionshapeovr
- The decisionfunction value of a given sample was different depending on whether the decisionfunction was evaluated on the sample alone or on a batch containing this same sample due to the scaling used in decisionfunction 10440 by Jonathan Ohayon
- sklearnntree
- FEATURE Decision Trees can now be plotted with matplotlib using treeplottree without relying on the dot library removing a hardtoinstall dependency 8508 by Andreas Müller
 - FEATURE Decision Trees can now be exported in a human readable textual format using treeexporttext 6261 by Giuseppe Vettigli
 - FEATURE getnleaves andgetdepth have been added to treeBaseDecisionTree and consequently all estimators based on it including treeDecisionTreeClassifier treeDecisionTreeRegressor treeExtraTreeClassifier andtreeExtraTreeRegressor 12300 by Adrin Jalali
 - FIXTrees and forests did not previously predict multioutput classification targets with string labels despite accepting them in fit 11458 by Mitar Milutinovic
 - FIXFixed an issue with treeBaseDecisionTree and consequently all estimators based on it including treeDecisionTreeClassifier treeDecisionTreeRegressor treeExtraTreeClassifier andtreeExtraTreeRegressor where they used to exceed the given maxdepth by 1 while expanding the tree if maxleafnodes andmaxdepth were both specified by the user Please note that this also affects all ensemble methods using decision trees 12344 by Adrin Jalali
- 111 Version 0210 39

scikitlearn user guide Release 0213

- sklearnutils
- FEATURE utilsresample now accepts a stratify parameter for sampling according to class distributions 13549 by Nicolas Hug
 - API (Application Programming Interface) CHANGE Deprecated warnonddtype parameter from utilscheckarray andutilscheckXy Added explicit warning for dtype conversion in checkpairwisearrays if themetric being passed is a pairwise boolean metric 13382 by Prathmesh Savale
- Multiple modules
- MAJOR FEATURE Therepr method of all estimators used when calling printestimator has been entirely rewritten building on Python’s pretty printing standard library All parameters are printed by default but this can be altered with the printchangedonly option insklearnsetconfig 11705 by Nicolas Hug
 - MAJOR FEATURE Add estimators tags these are annotations of estimators that allow programmatic inspection of their capabilities such as sparse matrix support supported output types and supported methods Estimator tags also determine the tests that are run on an estimator when checkestimator is called Read more in theUser Guide 8022 by Andreas Müller
 - EFFICIENCY Memory copies are avoided when casting arrays to a different dtype in multiple estimators 11973 by Roman Yurchak
 - FIXFixed a bug in the implementation of the ourrandr helper function that was not behaving consistently across platforms 13422 by Madhura Parikh and Clément Doumouro
- Miscellaneous
- ENHANCEMENT Joblib is no longer vendored in scikitlearn and becomes a dependency Minimal supported version is joblib 011 however using version 013 is strongly recommended 13531 by Roman Yurchak
- 1114 Changes to estimator checks
- These changes mostly affect library developers
- Addcheckfitidempotent tocheckestimator which checks that when fitis called twice with the same data the ouput of predict predictproba transform and decisionfunction does not change 12328 by Nicolas Hug
 - Many checks can now be disabled or configured with Estimator Tags 8022 by Andreas Müller
- 1115 Code and Documentation Contributors
- Thanks to everyone who has contributed to the maintenance and improvement of the project since version 020 including
- adanhawth Aditya Vyas Adrin Jalali Agamemnon Krasoulis Albert Thomas Alberto Torres Alexandre Gramfort amourav Andrea Navarrete Andreas Mueller Andrew Nystrom assiaben Aurélien Bellet Bartosz Michałowski Bartosz Telenczuk bauks BenjaStudio bertrandhaut Bharat Raghunathan brentfagan Bryan Woods Cat Chenal Cheuk Ting Ho Chris Choe Christos Aridas Clément Doumouro Cole Smith Connossor Corey Levinson Dan Ellis Dan Stine Danylo Baibak datenkieker Denis Kataev Didi BarZev Dillon Gardner Dmitry Mottl Dmitry Vukolov Dougal J Sutherland Dowon drewmjohnton Dror Atariah Edward J Brown Ekaterina Krivich Eliza beth Sander Emmanuel Arias Eric Chang Eric Larson Erich Schubert esvhd Falak Feda Curic Federico Caselli

112 Version 0204

July 30 2019

This is a bugfix release with some bug fixes applied to version 0203

1121 Changelog

The bundled version of joblib was upgraded from 0130 to 0132

sklearncluster

•FIXFixed a bug in clusterKMeans where KMeans initialisation could rarely result in an IndexError

11756 by Joel Nothman

sklearncompose

•FIXFixed an issue in composeColumnTransformer where using DataFrames whose column order
differs between func fit and funcstransform could lead to silently passing incorrect columns to the
remainder transformer 14237 by Andreas Schuderer

sklearnmodelselection

•FIXFixed a bug where modelselectionStratifiedKFold shuffles each class’s samples with the
samerandomstate makingshuffleTrue ineffective 13124 by Hanmin Qin

112 Version 0204 41

scikitlearn user guide Release 0.21.3

sklearn.neighbors

- FIX Fixed a bug in neighbors.KernelDensity which could not be restored from a pickle if sample_weight had been used 13772 by Aditya Vyas

1.13 Version 0.20.3

March 1, 2019

This is a bugfix release with some minor documentation improvements and enhancements to features released in 0.20.0

1.13.1 Changelog

sklearn.cluster

- FIX Fixed a bug in cluster.KMeans where computation was single threaded when n_jobs = 1 or n_jobs = -1 12949 by Prabakaran Kumareshan

sklearn.compose

- FIX Fixed a bug in compose.ColumnTransformer to handle negative indexes in the columns list of the transformers 12946 by Pierre Talbot

sklearn.covariance

- FIX Fixed a regression in covariance.graphical_lasso so that the case n_features > 2 is handled correctly 13276 by Aurélien Bellet

sklearn.decomposition

- FIX Fixed a bug in decomposition.sparse_encode where computation was single threaded when n_jobs = 1 or n_jobs = -1 13005 by Prabakaran Kumareshan

sklearn.datasets

- EFFICIENCY sklearn.datasets.fetch_openml now loads data by streaming avoiding high memory usage 13312 by Joris Van den Bossche

sklearn.feature_extraction

- FIX Fixed a bug in feature_extraction.text.CountVecorizer which would result in the sparse feature matrix having conflicting indices and indices precisions under very large vocabularies 11295 by Gabriel Vacaliuc

4.2 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

sklearnimpute

•FIXadd support for nonnumeric data in sklearnimputeMissingIndicator which was not supported while sklearnimputeSimpleImputer was supporting this for some imputation strategies 13046 by Guillaume Lemaitre

sklearnlinearmodel

•FIXFixed a bug in linearmodelMultiTaskElasticNet andlinearmodel

MultiTaskLasso which were breaking when warmstart True 12360 by Aakanksha Joshi sklearnpreprocessing

•FIXFixed a bug in preprocessingKBinsDiscretizer wherestrategykmeans fails with an error during transformation due to unsorted bin edges 13134 by Sandro Casagrande

•FIXFixed a bug in preprocessingOneHotEncoder where the deprecation of categoricalfeatures was handled incorrectly in combination with handleunknownignore 12881 by Joris Van den Bossche

•FIXBins whose width are too small ie 1e8 are removed with a warning in preprocessing KBinsDiscretizer 13165 by Hanmin Qin

sklearnsvm

•FIXFixed a bug in svmSVC svmNuSVC svmSVR svmNuSVR andsvmOneClassSVM where the scale option of parameter gamma is erroneously defined as 1 / nfeatures Xstd It's now defined as1 / nfeatures Xvar 13221 by Hanmin Qin

1132 Code and Documentation Contributors

114 Version 0202

December 20 2018

This is a bugfix release with some minor documentation improvements and enhancements to features released in 0200

114 Version 0202 43

scikitlearn user guide Release 0213

1141 Changed models

The following estimators and functions when fit with the same data and parameters may produce different models from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in random sampling procedures

- sklearnneighbors whenmetricjaccard bug fix
- use ofseuclidean ormahalanobis metrics in some cases bug fix

1142 Changelog

sklearncompose

- FIXFixed an issue in composemakecolumntransformer which raises unexpected error when columns is pandas Index or pandas Series 12704 by Hanmin Qin

sklearnmetrics

- FIX Fixed a bug in metricspairwiselocaldistances andmetrics

pairwiselocaldistanceschunked where parameters Vofseuclidean andVlofmahalanobis

metrics were computed after the data was split into chunks instead of being precomputed on whole data

12701 by Jeremie du Boisberranger

sklearnneighbors

- FIXFixedsklearnneighborsDistanceMetric jaccard distance function to return 0 when two all zero vectors are compared 12685 by Thomas Fan

sklearnutils

- FIXCallingutilscheckarray onpandasSeries with categorical data which raised an error in 0200 now returns the expected output again 12699 by Joris Van den Bossche

115 Version 0201

November 21 2018

This is a bugfix release with some minor documentation improvements and enhancements to features released in

0200 Note that we also include some API (Application Programming Interface) changes in this release so you might get some extra warnings after updating from 0200 to 0201

44 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

1151 Changed models

The following estimators and functions when fit with the same data and parameters may produce different models from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in random sampling procedures

- decompositionIncrementalPCA bug fix

1152 Changelog

sklearncluster

- EFFICIENCY makeclusterMeanShift no longer try to do nested parallelism as the overhead would hurt performance significantly when njobs 1 12159 by Olivier Grisel

- FIXFixed a bug in clusterDBSCAN with precomputed sparse neighbors graph which would add explicitly zeros on the diagonal even when already present 12105 by Tom Dupre la Tour

sklearncompose

- FIXFixed an issue in composeColumnTransformer when stacking columns with types not convertible to a numeric 11912 by Adrin Jalali

- API (Application Programming Interface) C HANGE composeColumnTransformer now applies the sparsethreshold even if all transformation results are sparse 12304 by Andreas Müller

- API (Application Programming Interface) C HANGE composemakecolumntransformer now expects transformer columns instead ofcolumns transformer to keep consistent with composeColumnTransformer 12339

by Adrin Jalali

sklearndatasets

- FIXdatasetsfetchopenml to correctly use the local cache 12246 by Jan N van Rijn

- FIXdatasetsfetchopenml to correctly handle ignore attributes and row id attributes 12330 by Jan N van Rijn

- FIXFixed integer overflow in datasetsmakeclassification for values of ninformative parameter larger than 64 10811 by Roman Feldbauer

- FIXFixed olivetti faces dataset DESCR attribute to point to the right location in datasets fetcholivettifaces 12441 by Jérémie du Boisberranger

- FIXdatasetsfetchopenml to retry downloading when reading from local cache fails 12517 by Thomas Fan

sklearncomposition

- FIXFixed a regression in decompositionIncrementalPCA where 0200 raised an error if the number of samples in the final batch for fitting IncrementalPCA was smaller than ncomponents 12234 by Ming Li

scikitlearn user guide Release 0213

sklearnensemble

- FIX Fixed a bug mostly affecting ensembleRandomForestClassifier where classweightbalancedsubsample failed with more than 32 classes 12165 by Joel Nothman
- FIX Fixed a bug affecting ensembleBaggingClassifier ensembleBaggingRegressor and ensembleIsolationForest where maxfeatures was sometimes rounded down to zero 12388

by Connor Tann

sklearnfeatureextraction

- FIX Fixed a regression in v0200 where featureextractiontextCountVectorizer and other text vectorizers could error during stop words validation with custom preprocessors or tokenizers 12393 by Roman Yurchak

sklearnlinearmodel

- FIX linearmodelSGDClassifier and variants with earlystoppingTrue would not use a consistent validation split in the multiclass case and this would cause a crash when using those estimators as part of parallel parameter search or crossvalidation 12122 by Olivier Grisel
- FIX Fixed a bug affecting SGDClassifier in the multiclass case Each oneversusall step is run in a joblibParallel call and mutating a common parameter causing a segmentation fault if called within a backend using processes and not threads We now use requiresharedmem at thejoblibParallel instance creation 12518 by Pierre Glaser and Olivier Grisel

sklearnmetrics

- FIX Fixed a bug in metricspairwisepairwisedistancesargminmin which returned the square root of the distance when the metric parameter was set to “euclidean” 12481 by Jérémie du Boisber

ranger

- FIX Fixed a bug in metricspairwisepairwisedistanceschunked which didn’t ensure the diagonal is zero for euclidean distances 12612 by Andreas Müller
- API (Application Programming Interface) C HANGE Themetricscalinskiharabaszscore has been renamed to metricscalinskiharabaszscore and will be removed in version 023 12211 by Lisa Thomas Mark Hannel

and Melissa Ferrari

sklearnmixture

- FIX Ensure that the fitpredict method of mixtureGaussianMixture andmixtureBayesianGaussianMixture always yield assignments consistent with fit followed by predict even if the convergence criterion is too loose or not met 12451 by Olivier Grisel

sklearnneighbors

- FIX force the parallelism backend to threading forneighborsKDTree andneighborsBallTree in Python 27 to avoid pickling errors caused by the serialization of their methods 12171 by Thomas Moreau

46 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

sklearnpreprocessing

- FIXFixed bug in preprocessingOrdinalEncoder when passing manually specified categories 12365 by Joris Van den Bossche
 - FIXFixed bug in preprocessingKBinsDiscretizer where thetransform method mutates the encoder attribute The transform method is now thread safe 12514 by Hanmin Qin
 - FIXFixed a bug in preprocessingPowerTransformer where the YeoJohnson transform was incorrect for lambda parameters outside of 0 2 12522 by Nicolas Hug
 - FIXFixed a bug in preprocessingOneHotEncoder where transform failed when set to ignore unknown numpy strings of different lengths 12471 by Gabriel Marzinotto
 - API (Application Programming Interface) C HANGE The default value of the method argument in preprocessingpowertransform will be changed from boxcox toyeojohnson to matchpreprocessingPowerTransformer in version 023 A FutureWarning is raised when the default value is used 12317 by Eric Chang
- sklearnutils
- FIXUse float64 for mean accumulator to avoid floating point precision issues in preprocessing StandardScaler anddecompositionIncrementalPCA when using float32 datasets 12338 by bauks
 - FIXCallingutilscheckarray onpandasSeries which raised an error in 0200 now returns the expected output again 12625 by Andreas Müller

Miscellaneous

- FIXWhen using site joblib by setting the environment variable SKLEARNSITEJOBLIB added compatibility with joblib 011 in addition to 012 12350 by Joel Nothman and Roman Yurchak
 - FIXMake sure to avoid raising FutureWarning when calling npvstack with numpy 116 and later use list comprehensions instead of generator expressions in many locations of the scikitlearn code base 12467 by Olivier Grisel
 - API (Application Programming Interface) C HANGE Removed all mentions of sklearnexternalsjoblib and deprecated joblib methods exposed in sklearnutils except for utilsparallelbackend andutils registerparallelbackend which allow users to configure parallel computation in scikitlearn Other functionalities are part of joblib package and should be used directly by installing it The goal of this change is to prepare for unvendoring joblib in future version of scikitlearn 12345 by Thomas Moreau
- 1153 Code and Documentation Contributors

115 Version 0201 47

scikitlearn user guide Release 0213

116 Version 0200

September 25 2018

This release packs in a mountain of bug fixes features and enhancements for the Scikitlearn library and improvements to the documentation and examples Thanks to our contributors

This release is dedicated to the memory of Raghav Rajagopalan

Warning Version 020 is the last version of scikitlearn to support Python 27 and Python 34 Scikitlearn 021 will require Python 35 or higher

1161 Highlights

We have tried to improve our support for common datascience usecases including missing values categorical variables heterogeneous data and featurerepresentations with unusual distributions Missing values in features represented by NaNs are now accepted in columnwise preprocessing such as scalers Each feature is fitted disregarding NaNs and data containing NaNs can be transformed The new impute module provides estimators for learning despite missing data

ColumnTransformer handles the case where different features or columns of a pandasDataFrame need different preprocessing String or pandas Categorical columns can now be encoded with OneHotEncoder or OrdinalEncoder

TransformedTargetRegressor helps when the regression target needs to be transformed to be modeled

PowerTransformer andKBinsDiscretizer joinQuantileTransformer as nonlinear transformations

Beyond this we have added sampleweight support to several estimators including KMeans

BayesianRidge andKernelDensity and improved stopping criteria in others including MLPRegressor

GradientBoostingRegressor andSGDRegressor

This release is also the first to be accompanied by a Glossary of Common Terms and API (Application Programming Interface) Elements developed by Nothman The glossary is a reference resource to help users and contributors become familiar with the terminology and conventions used in Scikitlearn

Sorry if your contribution didn't make it into the highlights There's a lot here

1162 Changed models

The following estimators and functions when fit with the same data and parameters may produce different models from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in random sampling procedures

- clusterMeanShift bug fix
 - decompositionIncrementalPCA in Python 2 bug fix
 - decompositionSparsePCA bug fix
 - ensembleGradientBoostingClassifier bug fix affecting feature importances
 - isotonicIsotonicRegression bug fix
 - linearmodelARDRegression bug fix
 - linearmodelLogisticRegressionCV bug fix
 - linearmodelOrthogonalMatchingPursuit bug fix
- 48 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- linearmodelPassiveAggressiveClassifier bug fix
 - linearmodelPassiveAggressiveRegressor bug fix
 - linearmodelPerceptron bug fix
 - linearmodelSGDClassifier bug fix
 - linearmodelSGDRegressor bug fix
 - metricsrocaucscore bug fix
 - metricsroccurve bug fix
 - neuralnetworkBaseMultilayerPerceptron bug fix
 - neuralnetworkMLPClassifier bug fix
 - neuralnetworkMLPRegressor bug fix
 - The v0190 release notes failed to mention a backwards incompatibility with modelselection
- StratifiedKFold when shuffle=True due to 7823

Details are listed in the changelog below

While we are trying to better inform users by providing this information we cannot assure that this list is complete

1163 Known Major Bugs

- 11924 linearmodelLogisticRegressionCV with solver lbfgs and multiclassmultinomial may be nondeterministic or otherwise broken on macOS This appears to be the case on Travis CI servers but has not been confirmed on personal MacBooks This issue has been present in previous releases
- 9354 metrics pairwise euclidean distances which is used several times throughout the library gives results with poor precision which particularly affects its use with 32bit float inputs This became more problematic in versions 018 and 019 when some algorithms were changed to avoid casting 32bit data into 64bit

1164 Changelog

Support for Python 3.3 has been officially dropped

sklearn.cluster

- MAJOR FEATURE clusterAgglomerativeClustering now supports Single Linkage clustering via linkage='single' 9372 by Leland McInnes and Steve Astels
- FEATURE clusterKMeans and clusterMiniBatchKMeans now support sample weights via new parameter sample_weight in fit function 10933 by Johannes Hansen
- EFFICIENCY clusterKMeans clusterMiniBatchKMeans and clusterkmeans passed with algorithm='full' now enforces row-major ordering improving runtime 10471 by Gaurav Dhingra
- EFFICIENCY clusterDBSCAN now is parallelized according to n_jobs regardless of algorithm 8003 by Joël Billaud
- ENHANCEMENT clusterKMeans now gives a warning if the number of distinct clusters found is smaller than n_clusters This may occur when the number of distinct points in the data set is actually smaller than the number of clusters one is looking for 10059 by Christian Braune

116 Version 0200 49

scikitlearn user guide Release 0213

- FIXFixed a bug where the fit method ofclusterAffinityPropagation stored cluster centers as 3d array instead of 2d array in case of nonconvergence For the same class fixed undefined and arbitrary behavior in case of training data where all samples had equal similarity 9612 By Jonatan Samoocha
 - FIXFixed a bug in clusterspectralclustering where the normalization of the spectrum was using a division instead of a multiplication 8129 by Jan Margeta Guillaume Lemaitre and Devansh D
 - FIXFixed a bug in clusterkmeanselkan where the returned iteration was 1 less than the correct value Also added the missing niter attribute in the docstring of clusterKMeans 11353 by Jeremie du Boisberranger
 - FIXFixed a bug in clustermeanshift where the assigned labels were not deterministic if there were multiple clusters with the same intensities 11901 by Adrin Jalali
 - API (Application Programming Interface) C HANGE Deprecate poolingfunc unused parameter in cluster AgglomerativeClustering 9875 by Kumar Ashutosh
- sklearncompose
- New module
 - MAJOR FEATURE AddedcomposeColumnTransformer which allows to apply different transformers to different columns of arrays or pandas DataFrames 9012 by Andreas Müller and Joris Van den Bossche and 11315 by Thomas Fan
 - MAJOR FEATURE Added thecomposeTransformedTargetRegressor which transforms the target y before fitting a regression model The predictions are mapped back to the original space via an inverse transform 9041 by Andreas Müller and Guillaume Lemaitre
- sklearncovariance
- EFFICIENCY Runtime improvements to covarianceGraphicalLasso 9858 by Steven Brown
 - API (Application Programming Interface) C HANGE Thecovariancegraphlasso covarianceGraphLasso andcovariance GraphLassoCV have been renamed to covariancegraphicallasso covariance GraphicalLasso andcovarianceGraphicalLassoCV respectively and will be removed in version 022 9993 by Artiem Krinitsyn
- sklearndatasets
- MAJOR FEATURE Addeddatasetsfetchopenml to fetch datasets from OpenML OpenML is a free open data sharing platform and will be used instead of mldata as it provides better service availability 9908 by Andreas Müller and Jan N van Rijn
 - FEATURE Indatasetsmakeblobs one can now pass a list to the nsamples parameter to indicate the number of samples to generate per cluster 8617 by Maskani Filali Mohamed and Konstantinos Katrioplas
 - FEATURE Addfilename attribute to datasets that have a CSV file 9101 by alex33 and Maskani Filali Mohamed
 - FEATURE returnXy parameter has been added to several dataset loaders 10774 by Chris Catalfo
 - FIXFixed a bug in datasetsloadboston which had a wrong data point 10795 by Takeshi Yoshizawa
 - FIXFixed a bug in datasetsloadiris which had two wrong data points 11082 by Sadhana Srini vasan and Hanmin Qin
- 50 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- FIXFixed a bug in datasetsfetchkddcup99 where data were not properly shuffled 9731 by Nicolas Goix
 - FIXFixed a bug in datasetsmakecircles where no odd number of data points could be generated 10045 by Christian Braune
 - API (Application Programming Interface) CHANGE Deprecated sklearn.datasets.fetch_ml_data to be removed in version 0.22 ml data.org is no longer operational Until removal it will remain possible to load cached datasets 11466 by Joel Nothman
 - sklearn.decomposition
 - FEATURE decompositiondictlearning functions and models now support positivity constraints This applies to the dictionary and sparse code 6374 by John Kirkham
 - FEATURE FIXdecompositionSparsePCA now exposes normalize_components When set to True the train and test data are centered with the train mean respectively during the fit phase and the transform phase This fixes the behavior of SparsePCA When set to False which is the default the previous abnormal behaviour still holds The False value is for backward compatibility and should not be used 11585 by Ivan Panico
 - EFFICIENCY Efficiency improvements in decompositiondictlearning 11420 and others by John Kirkham
 - FIXFix for uninformative error in decompositionIncrementalPCA now an error is raised if the number of components is larger than the chosen batch size The n_components=None case was adapted accordingly 6452 By Wally Gauze
 - FIXFixed a bug where the partial_fit method of decompositionIncrementalPCA used integer division instead of float division on Python 2 9492 by James Bourbeau
 - FIXIn decompositionPCA selecting a n_components parameter greater than the number of samples now raises an error Similarly the n_components=None case now selects the minimum of n_samples and n_features 8484 by Wally Gauze
 - FIXFixed a bug in decompositionPCA where users will get unexpected error with large datasets when n_components=ml on Python 3 versions 9886 by Hanmin Qin
 - FIXFixed an underflow in calculating KLdivergence for decompositionNMF 10142 by Tom Dupre la Tour
 - FIXFixed a bug in decompositionSparseCoder when running OMP sparse coding in parallel using read-only memory mapped data structures 5956 by Vignesh Birodkar and Olivier Grisel
 - sklearn.discriminantanalysis
 - EFFICIENCY Memory usage improvement for class_means and class_cov in discriminantanalysis 10898 by Nanxin Chen
 - sklearn.dummy
 - FEATURE dummyDummyRegressor now has a return_std option in its predict method The returned standard deviations will be zeros
 - FEATURE dummyDummyClassifier and dummyDummyRegressor now only require X to be an object with finite length or shape 9832 by Vrishank Bhardwaj
- 116 Version 0.20.51

scikitlearn user guide Release 0213

- FEATURE dummyDummyClassifier anddummyDummyRegressor can now be scored without sup
plying test samples 11951 by Rüdiger Busche
sklearnensemble
 - FEATURE ensembleBaggingRegressor andensembleBaggingClassifier can now be fit
with missingnonfinite values in X andor multioutput Y to support wrapping pipelines that perform their
own imputation 9707 by Jimmy Wan
 - FEATURE ensembleGradientBoostingClassifier and ensemble
GradientBoostingRegressor now support early stopping via niternochange
validationfraction andtol 7071 by Raghav RV
 - FEATURE Addednamedestimators parameter in ensembleVotingClassifier to access fitted
estimators 9157 by Herilalaina Rakotoarison
 - FIXFixed a bug when fitting ensembleGradientBoostingClassifier orensemble
GradientBoostingRegressor withwarmstartTrue which previously raised a segmentation fault
due to a nonconversion of CSC matrix into CSR (Compressed Sparse Row) format expected by decisionfunction Similarly
Fortranordered arrays are converted to Cordered arrays in the dense case 9991 by Guillaume Lemaitre
 - FIXFixed a bug in ensembleGradientBoostingRegressor andensemble
GradientBoostingClassifier to have feature importances summed and then normalized rather
than normalizing on a pertree basis The previous behavior overweighted the Gini importance of features that
appear in later stages This issue only affected feature importances 11176 by Gil Forsyth
 - API (Application Programming Interface) C HANGE The default value of the nestimators parameter of ensemble
RandomForestClassifier ensembleRandomForestRegressor ensemble
ExtraTreesClassifier ensembleExtraTreesRegressor and ensemble
RandomTreesEmbedding will change from 10 in version 020 to 100 in 022 A FutureWarning is
raised when the default value is used 11542 by Anna Ayzenshtat
 - API (Application Programming Interface) C HANGE Classes derived from ensembleBaseBagging The attribute estimatorssamples
will return a list of arrays containing the indices selected for each bootstrap instead of a list of arrays containing
the mask of the samples selected for each bootstrap Indices allows to repeat samples while mask does not allow
this functionality 9524 by Guillaume Lemaitre
 - FIXensembleBaseBagging where one could not deterministically reproduce fit result using the object
attributes when randomstate is set 9723 by Guillaume Lemaitre
sklearnfeatureextraction
 - FEATURE Enable the call to getfeaturenames in unfitted featureextractiontext
CountVectorizer initialized with a vocabulary 10908 by Mohamed Maskani
 - ENHANCEMENT idf can now be set on a featureextractiontextTfidfTransformer
10899 by Sergey Melderis
 - FIXFixed a bug in featureextractionimageextractpatches2d which would throw an
exception if maxpatches was greater than or equal to the number of all possible patches rather than simply
returning the number of possible patches 10101 by Varun Agrawal
 - FIXFixed a bug in featureextractiontextCountVectorizer featureextraction
textTfidfVectorizer featureextractiontextHashingVectorizer to support 64 bit
sparse array indexing necessary to process large datasets with more than $2 \cdot 10^9$ tokens words or ngrams
9147 by ClaesFredrik Mannby and Roman Yurchak
- 52 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- FIXFixed bug in featureextractiontextTfidfVectorizer which was ignoring the parameterdtype In addition featureextractiontextTfidfTransformer will preserve dtype for floating and raise a warning if dtype requested is integer 10441 by Mayur Kulkarni and Guillaume Lemaitre
 - sklearnfeatureselection
 - FEATURE Added select K best features functionality to featureselectionSelectFromModel 6689 by Nihar Sheth and Quazi Rahman
 - FEATURE Addedminfeaturestoselect parameter to featureselectionRFECV to bound evaluated features counts 11293 by Brent Yi
 - FEATURE featureselectionRFECV 's fit method now supports groups 9656 by Adam Greenhall
 - FIXFixed computation of nfeaturestocompute for edge case with tied CV (Cross-Validation) scores in featureselectionRFECV 9222 by Nick Hoh
 - sklearngaussianprocess
 - EFFICIENCY IngaussianprocessGaussianProcessRegressor methodpredict is faster when using returnstdTrue in particular more when called several times in a row 9234 by andrewww and Minghui Liu
 - sklearnimpute
 - New module adopting preprocessingImputer asimputeSimpleImputer with minor changes see under preprocessing below
 - MAJOR FEATURE AddedimputeMissingIndicator which generates a binary indicator for missing values 8075 by Maniteja Nandana and Guillaume Lemaitre
 - FEATURE TheimputeSimpleImputer has a new strategy constant to complete missing values with a fixed one given by the fillvalue parameter This strategy supports numeric and nonnumeric data and so does the mostfrequent strategy now 11211 by Jeremie du Boisberranger
 - sklearnisotonic
 - FIXFixed a bug in isotonicIsotonicRegression which incorrectly combined weights when fitting a model to data involving points with identical X values 9484 by Dallas Card
 - sklearnlinearmodel
 - FEATURE linearmodelSGDClassifier linearmodelSGDRegressor linearmodelPassiveAggressiveClassifier linearmodelPassiveAggressiveRegressor and linearmodelPerceptron now expose earlystopping validationfraction and niternochange parameters to stop optimization monitoring the score on a validation set A new learning rateadaptive strategy divides the learning rate by 5 each time niternochange consecutive epochs fail to improve the model 9043 by Tom Dupre la Tour
 - FEATURE Add sampleweight parameter to the fit method of linearmodelBayesianRidge for weighted linear regression 10112 by Peter St John
- 116 Version 0200 53

scikitlearn user guide Release 0213

- FIXFixed a bug in logisticlogisticregressionpath to ensure that the returned coefficients are correct when multiclassmultinomial. Previously some of the coefficients would override each other leading to incorrect results in linearmodelLogisticRegressionCV 11724 by Nicolas Hug
 - FIXFixed a bug in linearmodelLogisticRegression where when using the parameter multiclassmultinomial thepredictproba method was returning incorrect probabilities in the case of binary outcomes 9939 by Roger Westover
 - FIXFixed a bug in linearmodelLogisticRegressionCV where thescore method always computes accuracy not the metric given by the scoring parameter 10998 by Thomas Fan
 - FIXFixed a bug in linearmodelLogisticRegressionCV where the ‘ovr’ strategy was always used to compute crossvalidation scores in the multiclass setting even if multinomial was set 8720 by William de Vazelhes
 - FIXFixed a bug in linearmodelOrthogonalMatchingPursuit that was broken when setting normalizeFalse 10071 by Alexandre Gramfort
 - FIXFixed a bug in linearmodelARDRegression which caused incorrectly updated estimates for the standard deviation and the coefficients 10153 by Jörg Döpfert
 - FIXFixed a bug in linearmodelARDRegression andlinearmodelBayesianRidge which caused NaN predictions when fitted with a constant target 10095 by Jörg Döpfert
 - FIXFixed a bug in linearmodelRidgeClassifierCV where the parameter storecvvalues was not implemented though it was documented in cvvalues as a way to set up the storage of cross validation values for different alphas 10297 by Mabel VillalbalJiménez
 - FIXFixed a bug in linearmodelElasticNet which caused the input to be overridden when using parametercopyXTrue andcheckinputFalse 10581 by Yacine Mazari
 - FIXFixed a bug in sklearnlinearmodelLasso where the coefficient had wrong shape when fitinterceptFalse 10687 by Martin Hahn
 - FIXFixed a bug in sklearnlinearmodelLogisticRegression where the multiclassmultinomial with binary output with warmstartTrue 10836 by Aishwarya Srinivasan
 - FIXFixed a bug in linearmodelRidgeCV where using integer alphas raised an error 10397 by Mabel VillalbalJiménez
 - FIXFixed condition triggering gap computation in linearmodelLasso andlinearmodelElasticNet when working with sparse matrices 10992 by Alexandre Gramfort
 - FIX Fixed a bug in linearmodelSGDClassifier linearmodelSGDRegressor linearmodelPassiveAggressiveClassifier linearmodelPassiveAggressiveRegressor andlinearmodelPerceptron where the stopping criterion was stopping the algorithm before convergence A parameter niternochange was added and set by default to 5 Previous behavior is equivalent to setting the parameter to 1 9043 by Tom Dupre la Tour
 - FIXFixed a bug where liblinear and libsvmbased estimators would segfault if passed a scipysparse matrix with 64bit indices They now raise a ValueError 11327 by Karan Dhingra and Joel Nothman
 - API (Application Programming Interface) C HANGE The default values of the solver andmulticlass parameters of linearmodelLogisticRegression will change respectively from liblinear andovr in version 020 to lbfgs andauto in version 022 A FutureWarning is raised when the default values are used 11905 by Tom Dupre la Tour and Joel Nothman
 - API (Application Programming Interface) C HANGE DeprecatepositiveTrue option inlinearmodelLars as the underlying implementation is broken Use linearmodelLasso instead 9837 by Alexandre Gramfort
- 54 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- API (Application Programming Interface) C HANGE niter may vary from previous releases in linearmodelLogisticRegression withsolverbfgs andlinearmodelHuberRegressor For Scipy 100 the optimizer could perform more than the requested maximum number of iterations Now both estimators will report at most maxiter iterations even if more were performed 10723 by Joel Nothman

sklearnmanifold

- EFFICIENCY Speed improvements for both ‘exact’ and ‘barneshut’ methods in manifoldTSNE 10593 and 10610 by Tom Dupre la Tour

- FEATURE Support sparse input in manifoldIsomapfit 8554 by Leland McInnes

- FEATURE manifoldtsnetrustworthiness accepts metrics other than Euclidean 9775 by William de Vazelhes

- FIXFixed a bug in manifoldspectralembedding where the normalization of the spectrum was using a division instead of a multiplication 8129 by Jan Margeta Guillaume Lemaitre and Devansh D

- API (Application Programming Interface) C HANGE F EATURE Deprecate precomputed parameter in function manifoldtsne trustworthiness Instead the new parameter metric should be used with any compatible metric including ‘precomputed’ in which case the input matrix Xshould be a matrix of pairwise distances or squared distances 9775 by William de Vazelhes

- API (Application Programming Interface) C HANGE Deprecateprecomputed parameter in function manifoldtsnetrustworthiness Instead the new parameter metric should be used with any compatible metric including ‘precomputed’ in which case the input matrix Xshould be a matrix of pairwise distances or squared distances 9775 by William de Vazelhes

sklearnmetrics

- MAJOR FEATURE Added themetricsdaviesbouldinscore metric for evaluation of clustering models without a ground truth 10827 by Luis Osa

- MAJOR FEATURE Added the metricsbalancedaccuracy score metric and a corresponding balancedaccuracy scorer for binary and multiclass classification 8066 by xyguo and Aman Dalmia and 10587 by Joel Nothman

- FEATURE Partial AUC is available via maxfpr parameter in metricsrocaucscore 3840 by Alexander Niederbühl

- FEATURE A scorer based on metricsbrierscoreloss is also available 9521 by Hanmin Qin

- FEATURE Added control over the normalization in metricsnormalizedmutualinfoscore and metricsadjustedmutualinfoscore via theaveragemethod parameter In version 022 the default normalizer for each will become the arithmetic mean of the entropies of each clustering 11124 by Arya McCarthy

- FEATURE Addedoutputdict parameter in metricsclassificationreport to return classification statistics as dictionary 11160 by Dan Barkhorn

- FEATURE metricsclassificationreport now reports all applicable averages on the given data including micro macro and weighted average as well as samples average for multilabel data 11679 by Alexander Pacha

- FEATURE metricsaverageprecisionscore now supports binary ytrue other than0 1 or 1 1 throughposlabel parameter 9980 by Hanmin Qin

- FEATURE metricslabelrankingaverageprecisionscore now supports sampleweight 10845 by Jose PerezParras Toledano

116 Version 0200 55

scikitlearn user guide Release 0213

- FEATURE Adddenseoutput parameter to metricspairwiselinearkernel When False and both inputs are sparse will return a sparse matrix 10999 by Taylor G Smith
 - EFFICIENCY metricssilhouettescore andmetricssilhouettesamples are more memory efficient and run faster This avoids some reported freezes and MemoryErrors 11135 by Joel Nothman
 - FIXFixed a bug in metricsprecisionrecallfscoresupport when truncated rangenlabels is passed as value for labels 10377 by Gaurav Dhingra
 - FIXFixed a bug due to floating point error in metricsrocaucscore with noninteger sample weights 9786 by Hanmin Qin
 - FIXFixed a bug where metricsroccurve sometimes starts on yaxis instead of 0 0 which is inconsistent with the document and other implementations Note that this will not influence the result from metricsrocaucscore 10093 by alexryndin and Hanmin Qin
 - FIXFixed a bug to avoid integer overflow Casted product to 64 bits integer in metrics mutualinfoscore 9772 by Kumar Ashutosh
 - FIXFixed a bug where metricsaverageprecisionscore will sometimes return nan when sampleweight contains 0 9980 by Hanmin Qin
 - FIXFixed a bug in metricsfowlkesmallowsscore to avoid integer overflow Casted return value ofContingency Matrix toint64 and computed product of square roots rather than square root of product 9515 by Alan Liddell and Manh Dao
 - API (Application Programming Interface) C HANGE Deprecatereorder parameter in metricsauc as it's no longer required for metrics rocaucscore Moreover using reorderTrue can hide bugs due to floating point error in the input 9851 by Hanmin Qin
 - API (Application Programming Interface) C HANGE Inmetricsnormalizedmutualinfoscore andmetrics adjustedmutualinfoscore warn that averagemethod will have a new default value In version 022 the default normalizer for each will become the arithmetic mean of the entropies of each clustering Currently metricsnormalizedmutualinfoscore uses the default of averagemethodgeometric andmetricsadjustedmutualinfoscore uses the default ofaveragemethodmax to match their behaviors in version 019 11124 by Arya McCarthy
 - API (Application Programming Interface) C HANGE Thebatchsize parameter to metricspairwisedistancesargminmin and metricspairwisedistancesargmin is deprecated to be removed in v022 It no longer has any effect as batch size is determined by global workingmemory config See Limiting Working Memory 10280 by Joel Nothman and Aman Dalmia
 - sklearnmixture
 - FEATURE Added function fitpredict toixtureGaussianMixture andmixture GaussianMixture which is essentially equivalent to calling fitand predict 10336 by Shu Haoran and Andrew Peng
 - FIXFixed a bug in mixtureBaseMixture where the reported niter was missing an iteration It affectedmixtureGaussianMixture andmixtureBayesianGaussianMixture 10740 by Erich Schubert and Guillaume Lemaitre
 - FIXFixed a bug in mixtureBaseMixture and its subclasses mixtureGaussianMixture and mixtureBayesianGaussianMixture where thelowerbound was not the max lower bound across all initializations when ninit 1 but just the lower bound of the last initialization 10869 by Aurélien Géron
- 56 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

sklearnmodelselection

- FEATURE Addreturnestimator parameter in modelselectioncrossvalidate to return estimators fitted on each split 9686 by Aurélien Bellet
 - FEATURE Newrefittime attribute will be stored in modelselectionGridSearchCV and modelselectionRandomizedSearchCV ifrefit is set toTrue This will allow measuring the complete time it takes to perform hyperparameter optimization and refitting the best model on the whole dataset 11310 by Matthias Feurer
 - FEATURE Exposeerrorscore parameter in modelselectioncrossvalidate modelselectioncrossvalscore modelselectionlearningcurve and modelselectionvalidationcurve to control the behavior triggered when an error occurs in modelselectionfitandscore 11576 by Samuel O Ronsin
 - FEATURE BaseSearchCV now has an experimental private interface to support customized parameter search strategies through its runsearch method See the implementations in modelselection GridSearchCV andmodelselectionRandomizedSearchCV and please provide feedback if you use this Note that we do not assure the stability of this API (Application Programming Interface) beyond version 020 9599 by Joel Nothman
 - ENHANCEMENT Add improved error message in modelselectioncrossvalscore when multiple metrics are passed in scoring keyword 11006 by Ming Li
 - API (Application Programming Interface) C HANGE The default number of crossvalidation folds cvand the default number of splits nsplits in themodelselectionKfold like splitters will change from 3 to 5 in 022 as 3fold has a lot of variance 11557 by Alexandre Boucaud
 - API (Application Programming Interface) C HANGE The default of iid parameter of modelselectionGridSearchCV and modelselectionRandomizedSearchCV will change from True toFalse in version 022 to correspond to the standard definition of crossvalidation and the parameter will be removed in version 024 altogether This parameter is of greatest practical significance where the sizes of different test sets in crossvalidation were very unequal ie in groupbased CV (Cross-Validation) strategies 9085 by Laurent Direr and Andreas Müller
 - API (Application Programming Interface) C HANGE The default value of the errorscore parameter in modelselectionGridSearchCV andmodelselectionRandomizedSearchCV will change to npNaN in version 022 10677 by Kirill Zhdanovich
 - API (Application Programming Interface) C HANGE Changed ValueError exception raised in modelselectionParameterSampler to a UserWarning for case where the class is instantiated with a greater value of niter than the total space of parameters in the parameter grid niter now acts as an upper bound on iterations 10982 by Juliet Lawton
 - API (Application Programming Interface) C HANGE Invalid input for modelselectionParameterGrid now raises TypeError 10928 by Solutus Immensus
- sklearnmultioutput
- MAJOR FEATURE AddedmultioutputRegressorChain for multitarget regression 9257 by Kumar Ashutosh
- sklearnnaivebayes
- MAJOR FEATURE AddednaivebayesComplementNB which implements the Complement Naive Bayes classifier described in Rennie et al 2003 8190 by Michael A Alcorn
 - FEATURE Addvarsmoothing parameter in naivebayesGaussianNB to give a precise control over variances calculation 9681 by Dmitry Mottl
- 116 Version 0200 57

scikitlearn user guide Release 0213

- FIXFixed a bug in naivebayesGaussianNB which incorrectly raised error for prior list which summed to 1 10005 by Gaurav Dhingra
- FIXFixed a bug in naivebayesMultinomialNB which did not accept vector valued pseudocounts alpha 10346 by Tobias Madsen
- sklearnneighbors
- EFFICIENCY neighborsRadiusNeighborsRegressor and neighborsRadiusNeighborsClassifier are now parallelized according to njobs regardless of algorithm 10887 by Joël Billaud
- EFFICIENCY Nearest neighbors query methods are now more memory efficient when algorithmbrute 11136 by Joel Nothman and Aman Dalmia
- FEATURE Addsampleweight parameter to the fit method of neighborsKernelDensity to enable weighting in kernel density estimation 4394 by Samuel O Ronsin
- FEATURE Novelty detection with neighborsLocalOutlierFactor Add a novelty parameter toneighborsLocalOutlierFactor When novelty is set to True neighborsLocalOutlierFactor can then be used for novelty detection ie predict on new unseen data Available prediction methods are predict decisionfunction andscoresamples By default novelty is set toFalse and only the fitpredict method is available By Albert Thomas
- FIXFixed a bug in neighborsNearestNeighbors where fitting a NearestNeighbors model fails when a the distance metric used is a callable and b the input to the NearestNeighbors model is sparse 9579 by Thomas Kober
- FIXFixed a bug so predict inneighborsRadiusNeighborsRegressor can handle empty neighbors set when using non uniform weights Also raises a new warning when no neighbors are found for samples 9655 by Andreas BjerreNielsen
- FIX EFFICIENCY Fixed a bug in KDTree construction that results in faster construction and querying times 11556 by Jake VanderPlas
- FIXFixed a bug in neighborsKDTree andneighborsBallTree where pickled tree objects would change their type to the super class BinaryTree 11774 by Nicolas Hug
- sklearnneuralnetwork
- FEATURE Add niternochange parameter in neuralnetworkBaseMultilayerPerceptron neuralnetworkMLPRegressor andneuralnetworkMLPClassifier to give control over maximum number of epochs to not meet tol improvement 9456 by Nicholas Nadeau
- FIXFixed a bug in neuralnetworkBaseMultilayerPerceptron neuralnetworkMLPRegressor andneuralnetworkMLPClassifier with newniternochange parameter now at 10 from previously hardcoded 2 9456 by Nicholas Nadeau
- FIXFixed a bug in neuralnetworkMLPRegressor where fitting quit unexpectedly early due to local minima or fluctuations 9456 by Nicholas Nadeau
- sklearnpipeline
- FEATURE Thepredict method of pipelinePipeline now passes keyword arguments on to the pipeline's last estimator enabling the use of parameters such as returnstd in a pipeline with caution 9304 by Breno Freitas

scikitlearn user guide Release 0213

•API (Application Programming Interface) C HANGE pipelineFeatureUnion now supports drop as a transformer to drop features 11144 by Thomas Fan

sklearnpreprocessing

•MAJOR FEATURE ExpandedpreprocessingOneHotEncoder to allow to encode categorical string features as a numeric array using a onehot or dummy encoding scheme and added preprocessing OrdinalEncoder to convert to ordinal integers Those two classes now handle encoding of all feature types also handles stringvalued features and derives the categories based on the unique values in the features instead of the maximum value in the features 9151 and 10521 by Vighnesh Birodkar and Joris Van den Bossche

•MAJOR FEATURE AddedpreprocessingKBinsDiscretizer for turning continuous features into categorical or onehot encoded features 7668 9647 10195 10192 11272 11467 and 11505 by Henry Lin Hanmin Qin Tom Dupre la Tour and Giovanni Giuseppe Costa

•MAJOR FEATURE AddedpreprocessingPowerTransformer which implements the YeoJohnson and BoxCox power transformations Power transformations try to find a set of featurewise parametric transformations to approximately map data to a Gaussian distribution centered at zero and with unit variance This is useful as a variancestabilizing transformation in situations where normality and homoscedasticity are desirable 10210 by Eric Chang and Maniteja Nandana and 11520 by Nicolas Hug

•MAJOR FEATURE NaN values are ignored and handled in the following preprocessing methods preprocessingMaxAbsScaler preprocessingMinMaxScaler preprocessing RobustScaler preprocessingStandardScaler preprocessingPowerTransformer preprocessingQuantileTransformer classes and preprocessingmaxabsscale preprocessingminmaxscale preprocessingrobustscale preprocessing scale preprocessingpowertransform preprocessingquantiletransform functions respectively addressed in issues 11011 11005 11308 11206 11306 and 10437 By Lucija Gregov and Guillaume Lemaître

•FEATURE preprocessingPolynomialFeatures now supports sparse input 10452 by Aman Dalmia and Joel Nothman

•FEATURE preprocessingRobustScaler andpreprocessingrobustscale can be fitted using sparse matrices 11308 by Guillaume Lemaître

•FEATURE preprocessingOneHotEncoder now supports the getfeaturenames method to obtain the transformed feature names 10181 by Nirvan Anjirbag and Joris Van den Bossche

•FEATURE A parameter checkinverse was added to preprocessingFunctionTransformer to ensure that func andinversefunc are the inverse of each other 9399 by Guillaume Lemaître

•FEATURE Thetransform method ofsklearnpreprocessingMultiLabelBinarizer now ignores any unknown classes A warning is raised stating the unknown classes classes found which are ignored 10913 by Rodrigo Agundez

•FIXFixed bugs in preprocessingLabelEncoder which would sometimes throw errors when transform orinversetransform was called with empty arrays 10458 by Mayur Kulkarni

•FIXFix ValueError in preprocessingLabelEncoder when using inversetransform on unseen labels 9816 by Charlie Newey

•FIXFix bug inpreprocessingOneHotEncoder which discarded the dtype when returning a sparse matrix output 11042 by Daniel Morales

•FIXFixfit andpartialfit inpreprocessingStandardScaler in the rare case when withmeanFalse andwithstdFalse which was crashing by calling fit more than once and giving inconsistent results for mean whether the input was a sparse or a dense matrix mean will be set to None 116

Version 0200 59

scikitlearn user guide Release 0213

with both sparse and dense inputs nsamplesseen will be also reported for both input types 11235 by Guillaume Lemaitre

•API (Application Programming Interface) C HANGE Deprecate nvalues andcategoricalfeatures parameters and activefeatures featureindices andnvalues attributes of preprocessing OneHotEncoder Thenvalues parameter can be replaced with the new categories parameter and the attributes with the new categories attribute Selecting the categorical features with the categoricalfeatures parameter is now better supported using the compose ColumnTransformer 10521 by Joris Van den Bossche

•API (Application Programming Interface) C HANGE DeprecatepreprocessingImputer and move the corresponding module to impute SimpleImputer 9726 by Kumar Ashutosh

•API (Application Programming Interface) C HANGE Theaxis parameter that was in preprocessingImputer is no longer present in imputeSimpleImputer The behavior is equivalent to axis0 impute along columns Row wise imputation can be performed with FunctionTransformer eg FunctionTransformerlambda X

SimpleImputerfitttransformXTT 10829 by Guillaume Lemaitre and Gilberto Olimpio

•API (Application Programming Interface) C HANGE The NaN marker for the missing values has been changed between the preprocessing Imputer and the imputeSimpleImputer missingvaluesNaN should now be missingvaluesnpnan 11211 by Jeremie du Boisberranger

•API (Application Programming Interface) C HANGE InpreprocessingFunctionTransformer the default of validate will be from True toFalse in 022 10655 by Guillaume Lemaitre sklearnsvm

•FIXFixed a bug in svmSVC where when the argument kernel is unicode in Python2 the predict_proba method was raising an unexpected TypeError given dense inputs 10412 by Jiongyan Zhang

•API (Application Programming Interface) C HANGE Deprecaterandomstate parameter in svmOneClassSVM as the underlying implementation is not random 9497 by Albert Thomas

•API (Application Programming Interface) C HANGE The default value of gamma parameter of svmSVC NuSVC SVRNuSVR OneClassSVM will change from auto toscale in version 022 to account better for unscaled features 8361 by Gaurav Dhingra and Ting Neo

sklearnntree

•ENHANCEMENT Although private and hence not assured API (Application Programming Interface) stability treecriterion ClassificationCriterion andtreecriterionRegressionCriterion may now be imported and extended 10325 by Camil Staps

•FIXFixed a bug in treeBaseDecisionTree withsplitterbest where split threshold could become infinite when values in X were near infinite 10536 by Jonathan Ohayon

•FIXFixed a bug in treeMAE to ensure sample weights are being used during the calculation of tree MAE impurity Previous behaviour could cause suboptimal splits to be chosen since the impurity calculation considered all samples to be of equal weight importance 11464 by John Stott sklearnutils

•FEATURE utilscheckarray andutilscheckXy now haveacceptlargesparsed to control whether scipysparse matrices with 64bit indices should be rejected 11327 by Karan Dhingra and Joel Nothman

60 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- EFFICIENCY F IXAvoid copying the data in utilscheckarray when the input data is a memmap and copyFalse 10663 by Arthur Mensch and Loïc Estève
- API (Application Programming Interface) C HANGE utilscheckarray yield aFutureWarning indicating that arrays of bytesstrings will be interpreted as decimal numbers beginning in version 022 10229 by Ryan Lee
- Multiple modules
- FEATURE API (Application Programming Interface) C HANGE More consistent outlier detection API (Application Programming Interface) Add a score insvmOneClassSVM ensembleIsolationForest neighborsLocalOutlierFactor
- covarianceEllipticEnvelope It allows to access raw score functions from original parameters A new offset parameter allows to link scoresamples anddecisionfunction methods The contamination parameter of ensembleIsolationForest andneighbors LocalOutlierFactor decisionfunction methods is used to define this offset such that outliers resp inliers have negative resp positive decisionfunction values By default contamination is kept unchanged to 0.1 for a deprecation period In 0.22 it will be set to “auto” thus using methodspecific score offsets In covarianceEllipticEnvelope decisionfunction method the rawvalues parameter is deprecated as the shifted Mahalanobis distance will be always returned in 0.22 9015 by Nicolas Goix
- FEATURE API (Application Programming Interface) C HANGE Abehaviour parameter has been introduced in ensemble IsolationForest to ensure backward compatibility In the old behaviour the decisionfunction is independent of the contamination parameter A threshold attribute depending on the contamination parameter is thus used In the new behaviour the decisionfunction is dependent on the contamination parameter in such a way that 0 becomes its natural threshold to detect outliers Setting behaviour to “old” is deprecated and will not be possible in version 0.22 Beside the behaviour parameter will be removed in 0.24 11553 by Nicolas Goix
- API (Application Programming Interface) C HANGE Added convergence warning to svmLinearSVC andlinearmodel LogisticRegression whenverbose is set to 0 10881 by Alexandre Sevin
- API (Application Programming Interface) C HANGE Changed warning type from UserWarning toexceptionsConvergenceWarning for failing convergence in linearmodellogisticregressionpath linearmodel RANSACRegressor linearmodelridgeregression gaussianprocess GaussianProcessRegressor gaussianprocessGaussianProcessClassifier decompositionfastica crossdecompositionPLSCanonical cluster AffinityPropagation andclusterBirch 10306 by Jonathan Siebert
- Miscellaneous
- MAJOR FEATURE A new configuration parameter workingmemory was added to control memory consumption limits in chunked operations such as the new metricspairwisedistanceschunked See Limiting Working Memory 10280 by Joel Nothman and Aman Dalmia
- FEATURE The version of joblib bundled with Scikitlearn is now 0.12 This uses a new default multiprocessing implementation named loky While this may incur some memory and communication overhead it should provide greater crossplatform stability than relying on Python standard library multiprocessing 11741 by the joblib developers especially Thomas Moreau and Olivier Grisel
- FEATURE An environment variable to use the site joblib instead of the vendored one was added Environment variables The main API (Application Programming Interface) of joblib is now exposed in sklearnutils 11166 by Gael Varoquaux
- FEATURE Add almost complete PyPy 3 support Known unsupported functionalities are datasets loadsvmlightfile featureextractionFeatureHasher andfeatureextraction textHashingVectorizer For running on PyPy PyPy3v510 Numpy 1.14.0 and scipy 1.10.0 are required 11010 by Ronan Lamy and Roman Yurchak
- 116 Version 0.20.0 61

scikitlearn user guide Release 0213

- FEATURE A utility method sklearnshowversions was added to print out information relevant for debugging It includes the user system the Python executable the version of the main libraries and BLAS binding information 11596 by Alexandre Boucaud
- FIXFixed a bug when setting parameters on metaestimator involving both a wrapped estimator and its parameter 9999 by Marcus Voss and Joel Nothman
- FIXFixed a bug where calling sklearnbaseclone was not thread safe and could result in a “pop from empty list” error 9569 by Andreas Müller
- API (Application Programming Interface) CHANGE The default value of njobs is changed from 1toNone in all related functions and classes njobsNone meansunset It will generally be interpreted as njobs1 unless the current joblib Parallel backend context specifies otherwise See Glossary for additional information Note that this change happens immediately ie without a deprecation cycle 11741 by Olivier Grisel
- FIXFixed a bug in validation helpers where passing a Dask DataFrame results in an error 12462 by Zachariah Miller

1165 Changes to estimator checks

These changes mostly affect library developers

- Checks for transformers now apply if the estimator implements transform regardless of whether it inherits from sklearnbaseTransformerMixin 10474 by Joel Nothman
- Classifiers are now checked for consistency between decisionfunction and categorical predictions 10500 by Narine Kokhlikyan
- Allow tests in utilsestimatorcheckscheckestimator to test functions that accept pairwise data 9701 by Kyle Johnson
- Allowutilsestimatorcheckscheckestimator to check that there is no private settings apart from parameters during estimator initialization 9378 by Herilalaina Rakotoarison
- The set of checks in utilsestimatorcheckscheckestimator now includes a checksetparams test which checks that setparams is equivalent to passing parameters in init and warns if it encounters parameter validation 7738 by Alvin Chiang
- Add invariance tests for clustering metrics 8102 by Ankita Sinha and Guillaume Lemaitre
- Addcheckmethodssubsetinvariance tocheckestimator which checks that estimator methods are invariant if applied to a data subset 10428 by Jonathan Ohayon
- Add tests in utilsestimatorcheckscheckestimator to check that an estimator can handle readonly memmap input data 10663 by Arthur Mensch and Loïc Estève
- checksampleweightspandasseries now uses 8 rather than 6 samples to accommodate for the default number of clusters in clusterKMeans 10933 by Johannes Hansen
- Estimators are now checked for whether sampleweightNone equates to sampleweightnp.ones 11558 by Sergul Aydore

1166 Code and Documentation Contributors

117 Previous Releases 63

scikitlearn user guide Release 0213

This release is exclusively in order to support Python 37

Related changes

- niter may vary from previous releases in linearmodelLogisticRegression with solverlbfgs andlinearmodelHuberRegressor For Scipy 100 the optimizer could perform more than the requested maximum number of iterations Now both estimators will report at most maxiter iterations even if more were performed 10723 by Joel Nothman

1172 Version 0191

October 23 2017

This is a bugfix release with some minor documentation improvements and enhancements to features released in

0190

Note there may be minor differences in TSNE output in this release due to 9623 in the case where multiple samples have equal distance to some sample

Changelog

API (Application Programming Interface) changes

- Reverted the addition of metricsndcg_score and metrics_sdcg_score which had been merged into version 0190 by error The implementations were broken and undocumented
- return_train_score which was added to model_selection.GridSearchCV model_selection.RandomizedSearchCV and model_selection.cross_validate in version 0190 will be changing its default value from True to False in version 021 We found that calculating training score could have a great effect on cross validation runtime in some cases Users should explicitly set return_train_score to False if prediction or scoring functions are slow resulting in a deleterious effect on CV (Cross-Validation) runtime or to True if they wish to use the calculated scores 9677 by Kumar Ashutosh and Joel Nothman
- correlation_models and regression_models from the legacy gaussian processes implementation have been belatedly deprecated 9717 by Kumar Ashutosh

Bug fixes

- Avoid integer overflows in metrics_matthews_corrcoef 9693 by Sam Steingold
- Fixed a bug in the objective function for manifold_TSNE both exact and with the BarnesHut approximation when n_components > 3 9711 by goncalorodrigues
- Fix regression in model_selection.cross_val_predict where it raised an error with method_predict_proba for some probabilistic classifiers 9641 by James Bourbeau
- Fixed a bug where datasets_make_classification modified its input weights 9865 by Sachin Kelkar
- model_selection.StratifiedShuffleSplit now works with multioutput multiclass or multilabel data with more than 1000 columns 9922 by Charlie Brummitt
- Fixed a bug with nested and conditional parameter setting eg setting a pipeline step and its parameter at the same time 9945 by Andreas Müller and Joel Nothman

64 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

Regressions in 0190 fixed in 0191

- Fixed a bug where parallelised prediction in random forests was not threadsafe and could rarely result in arbitrary errors 9830 by Joel Nothman
- Fix regression in modelselectioncrossvalpredict where it no longer accepted X as a list 9600 by Rasul Kerimov
- Fixed handling of crossvalpredict for binary classification with methoddecisionfunction 9593 by Reiichiro Nakano and core devs
- Fix regression in pipelinePipeline where it no longer accepted steps as a tuple 9604 by Joris Van den Bossche
- Fix bug where niter was not properly deprecated leaving niter unavailable for interim use inlinearmodelSGDClassifier linearmodelSGDRegressor linearmodelPassiveAggressiveClassifier linearmodelPassiveAggressiveRegressor and linearmodelPerceptron 9558 by Andreas Müller
- Dataset fetchers make sure temporary files are closed before removing them which caused errors on Windows 9847 by Joan Massich
- Fixed a regression in manifoldTSNE where it no longer supported metrics other than ‘euclidean’ and ‘pre computed’ 9623 by Oli Blum

Enhancements

- Our test suite and utilsestimatorcheckscheckestimators can now be run without Nose in stalled 9697 by Joan Massich
- To improve usability of version 019’s pipelinePipeline cachingmemory now allows joblib Memory instances This make use of the new utilsvalidationcheckmemory helper issue 9584 by Kumar Ashutosh
- Some fixes to examples 9750 9788 9815
- Made a FutureWarning in SGDbased estimators less verbose 9802 by Vrishank Bhardwaj

August 12 2017

Highlights

We are excited to release a number of great new features including neighborsLocalOutlierFactor for anomaly detection preprocessingQuantileTransformer for robust feature transformation and themultioutputClassifierChain metaestimator to simply account for dependencies between classes

117 Previous Releases 65

scikitlearn user guide Release 0213

in multilabel problems We have some new algorithms in existing estimators such as multiplicative up
date indecompositionNMF and multinomial linearmodelLogisticRegression with L1 loss use
solversaga

Cross validation is now able to return the results from multiple metric evaluations The new modelselection
crossvalidate can return many scores on the test data as well as training set performance and timings and we
have extended the scoring andrefit parameters for gridrandomized search to handle multiple metrics
You can also learn faster For instance the new option to cache transformations inpipelinePipeline makes
grid search over pipelines including slow transformations much more efficient And you can predict faster if you're
sure you know what you're doing you can turn off validating that the input is finite using configcontext
We've made some important fixes too We've fixed a longstanding implementation error in metrics
averageprecisionscore so please be cautious with prior results reported from that function A number
of errors in the manifoldTSNE implementation have been fixed particularly in the default BarnesHut approx
imationsemisupervisedLabelSpreading andsemisupervisedLabelPropagation have had
substantial fixes LabelPropagation was previously broken LabelSpreading should now correctly respect its alpha
parameter

Changed models

The following estimators and functions when fit with the same data and parameters may produce different models
from the previous version This often occurs due to changes in the modelling logic bug fixes or enhancements or in
random sampling procedures

- clusterKMeans with sparse X and initial centroids given bug fix
- crossdecompositionPLSRegression withscaleTrue bug fix
- ensembleGradientBoostingClassifier andensembleGradientBoostingRegressor
whereminimpuritysplit is used bug fix
- gradient boosting lossquantile bug fix
- ensembleIsolationForest bug fix
- featureselectionSelectFdr bug fix
- linearmodelRANSACRegressor bug fix
- linearmodelLassoLars bug fix
- linearmodelLassoLarsIC bug fix
- manifoldTSNE bug fix
- neighborsNearestCentroid bug fix
- semisupervisedLabelSpreading bug fix
- semisupervisedLabelPropagation bug fix
- tree based models where minweightfractionleaf is used enhancement
- modelselectionStratifiedKFold withshuffleTrue this change due to 7823 was not men

tioned in the release notes at the time
Details are listed in the changelog below

While we are trying to better inform users by providing this information we cannot assure that this list is complete
66 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

Changelog

New features

Classifiers and regressors

- AddedmultioutputClassifierChain for multilabel classification By Adam Kleczewski
- Added solver saga that implements the improved version of Stochastic Average Gradient in linearmodelLogisticRegression andlinearmodelRidge It allows the use of L1 penalty with multinomial logistic loss and behaves marginally better than ‘sag’ during the first epochs of ridge and logistic regression 8446 by Arthur Mensch

Other estimators

- Added the neighborsLocalOutlierFactor class for anomaly detection based on nearest neighbors 5279 by Nicolas Goix and Alexandre Gramfort
- Added preprocessingQuantileTransformer class and preprocessing quantiletransform function for features normalization based on quantiles 8363 by Denis Engemann Guillaume Lemaître Olivier Grisel Raghav RV Thierry Guillemot and Gael Varoquaux
- The new solver mu implements a Multiply Update in decompositionNMF allowing the optimization of all betadivergences including the Frobenius norm the generalized KullbackLeibler divergence and the ItakuraSaito divergence 5295 by Tom Dupré la Tour

Model selection and evaluation

- modelselectionGridSearchCV andmodelselectionRandomizedSearchCV now support simultaneous evaluation of multiple metrics Refer to the Specifying multiple metrics for evaluation section of the user guide for more information 7388 by Raghav RV
- Added the modelselectioncrossvalidate which allows evaluation of multiple metrics This function returns a dict with more useful information from crossvalidation such as the train scores fit times and score times Refer to The crossvalidate function and multiple metric evaluation section of the userguide for more information 7388 by Raghav RV
- Addedmetricsmeansquaredlogerror which computes the mean square error of the logarithmic transformation of targets particularly useful for targets with an exponential trend 7655 by Karan Desai
- Addedmetricsdcgscore andmetricsndcgsgscore which compute Discounted cumulative gain DCG and Normalized discounted cumulative gain NDCG 7739 by David Gasquez
- Added the modelselectionRepeatedKFold andmodelselection RepeatedStratifiedKFold 8120 by Neeraj Gangwar

Miscellaneous

- Validation that input data contains no NaN or inf can now be suppressed using configcontext at your own risk This will save on runtime and may be particularly useful for prediction time 7548 by Joel Nothman
- Added a test to ensure parameter listing in docstrings match the functionclass signature 9206 by Alexandre Gramfort and Raghav RV

Enhancements

Trees and ensembles

- The minweightfractionleaf constraint in tree construction is now more efficient taking a fast path to declare a node a leaf if its weight is less than 2 the minimum Note that the constructed tree will be different from previous versions where minweightfractionleaf is used 7441 by Nelson Liu

scikitlearn user guide Release 0213

- ensembleGradientBoostingClassifier andensembleGradientBoostingRegressor now support sparse input for prediction 6101 by Ibraim Ganiev
 - ensembleVotingClassifier now allows changing estimators by using ensembleVotingClassifiersetparams An estimator can also be removed by setting it to None 7674 by Yichuan Liu
 - treeexportgraphviz now shows configurable number of decimal places 8698 by Guillaume Lemaitre
 - Addedflattenttransform parameter to ensembleVotingClassifier to change output shape of transform method to 2 dimensional 7794 by Ibraim Ganiev and Herilalaina Rakotoarison
 - Linear kernelized and related models
 - linearmodelSGDClassifier linearmodelSGDRegressor linearmodelPassiveAggressiveClassifier linearmodelPassiveAggressiveRegressor and linearmodelPerceptron now expose maxiter andtol parameters to handle convergence more preciselyniter parameter is deprecated and the fitted estimator exposes a niter attribute with actual number of iterations before convergence 5036 by Tom Dupre la Tour
 - Added average parameter to perform weight averaging in linearmodelPassiveAggressiveClassifier 4939 by Andrea Esuli
 - linearmodelRANSACRegressor no longer throws an error when calling fit if no inliers are found in its first iteration Furthermore causes of skipped iterations are tracked in newly added attributes nskips 7914 by Michael Horrell
 - IngaussianprocessGaussianProcessRegressor method predict is a lot faster with returnstdTrue 8591 by Hadrien Bertrand
 - Addedreturnstd topredict method oflinearmodelARDRegression andlinearmodelBayesianRidge 7838 by Sergey Feldman
 - Memory usage enhancements Prevent cast from float32 to float64 in linearmodelMultiTaskElasticNet linearmodelLogisticRegression when using newtoncg solver and linearmodelRidge when using svd sparsecg cholesky or lsqr solvers 8835 8061 by Joan Massich and Nicolas Cordier and Thierry Guillemot
 - Other predictors
 - Custom metrics for the neighbors binary trees now have fewer constraints they must take two 1darrays and return a float 6288 by Jake Vanderplas
 - algorithmauto inneighbors estimators now chooses the most appropriate algorithm for all input types and metrics 9145 by Herilalaina Rakotoarison and Reddy Chinthala
 - Decomposition manifold learning and clustering
 - clusterMiniBatchKMeans andclusterKMeans now use significantly less memory when assigning data points to their nearest cluster center 7721 by Jon Crall
 - decompositionPCA decompositionIncrementalPCA anddecompositionTruncatedSVD now expose the singular values from the underlying SVD They are stored in the attributesingularvalues like indecompositionIncrementalPCA 7685 by Tommy Löfstedt
 - decompositionNMF now faster when betaloss0 9277 by hongkahjun
 - Memory improvements for method barneshut inmanifoldTSNE 7089 by Thomas Moreau and Olivier Grisel
 - Optimization schedule improvements for BarnesHut manifoldTSNE so the results are closer to the one from the reference implementation lvdmaatenbhtsne by Thomas Moreau and Olivier Grisel
- 68 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Memory usage enhancements Prevent cast from float32 to float64 in decompositionPCA and decompositionrandomizedsvdlowrank 9067 by Raghav RV
 - Preprocessing and feature selection
 - Addednormorder parameter to featureselectionSelectFromModel to enable selection of the norm order when coef is more than 1D 6181 by Antoine Wendlinger
 - Added ability to use sparse matrices in featureselectionfregression withcenterTrue 8065 by Daniel Lejeune
 - Small performance improvement to ngram creation in featureextractiontext by binding methods for loops and specialcasing unigrams 7567 by Jaye Doepeke
 - Relax assumption on the data for the kernelapproximationSkewedChi2Sampler Since the SkewedChi2 kernel is defined on the open interval $-\infty$ to ∞ the transform function should not check whether $X \geq 0$ but whether X selfskewedness 7573 by Romain Brault
 - Made default kernel parameters kerneldependent in kernelapproximationNystroem 5229 by Saurabh Bansod and Andreas Müller
 - Model evaluation and metaestimators
 - pipelinePipeline is now able to cache transformers within a pipeline by using the memory constructor parameter 7990 by Guillaume Lemaitre
 - pipelinePipeline steps can now be accessed as attributes of its namedsteps attribute 8586 by Herilalaina Rakotoarison
 - Addedsampleweight parameter to pipelinePipelinescore 7723 by Mikhail Korobov
 - Added ability to set njobs parameter to pipelinemakeunion ATypeError will be raised for any other kwargs 8028 by Alexander Booth
 - modelselectionGridSearchCV modelselectionRandomizedSearchCV and modelselectioncrossvalscore now allow estimators with callable kernels which were previously prohibited 8005 by Andreas Müller
 - modelselectioncrossvalpredict now returns output of the correct shape for all values of the argumentmethod 7863 by Aman Dalmia
 - Addedshuffle andrandomstate parameters to shuffle training data before taking prefixes of it based on training sizes in modelselectionlearningcurve 7506 by Narine Kokhlikyan
 - modelselectionStratifiedShuffleSplit now works with multioutput multiclass or multilabel data 9044 by Vlad Niculae
 - Speed improvements to modelselectionStratifiedShuffleSplit 5991 by Arthur Mensch and Joel Nothman
 - Addshuffle parameter to modelselectiontraintestsplit 8845 by themrmax
 - multioutputMultiOutputRegressor andmultioutputMultiOutputClassifier now support online learning using partialfit issue8053 by Peng Yu
 - Addmaxtrainsize parameter to modelselectionTimeSeriesSplit 8282 by Aman Dalmia
 - More clustering metrics are now available through metricsgetscorer andscoring parameters 8117 by Raghav RV
 - A scorer based on metricsexplainedvariancescore is also available 9259 by Hanmin Qin
 - Metrics
 - metricsmatthewscorrcoef now support multiclass classification 8094 by Jon Crall
- 117 Previous Releases 69

scikitlearn user guide Release 0213

- Addsampleweight parameter to metricscohenkappascore 8335 by Victor Poughon

Miscellaneous

- utilscheckestimator now attempts to ensure that methods transform predict etc do not set attributes on the estimator 7533 by Ekaterina Krivich
- Added type checking to the acceptspare parameter in utilsvalidation methods This parameter now accepts only boolean string or listtuple of strings acceptspareNone is deprecated and should be replaced by acceptspareFalse 7880 by Josh Karnofsky
- Make it possible to load a chunk of an svmlight formatted file by passing a range of bytes to datasets loadsvmlightfile 935 by Olivier Grisel
- dummyDummyClassifier anddummyDummyRegressor now accept nonfinite features 8931 by Attractadore

Bug fixes

Trees and ensembles

- Fixed a memory leak in trees when using trees with criterionmae 8002 by Raghav RV
- Fixed a bug where ensembleIsolationForest uses an an incorrect formula for the average path length 8549 by Peter Wang
- Fixed a bug where ensembleAdaBoostClassifier throwsZeroDivisionError while fitting data with single class labels 7501 by Dominik Krzeminski
- Fixed a bug in ensembleGradientBoostingClassifier andensemble GradientBoostingRegressor where a float being compared to 00 usingcaused a divide by zero error 7970 by He Chen
- Fix a bug where ensembleGradientBoostingClassifier andensemble GradientBoostingRegressor ignored the minimpuritysplit parameter 8006 by Sebastian Pölsterl
- Fixedoobscore inensembleBaggingClassifier 8936 by Michael Lewis
- Fixed excessive memory usage in prediction for random forests estimators 8672 by Mike Benfield
- Fixed a bug where sampleweight as a list broke random forests in Python 2 8068 by xor
- Fixed a bug where ensembleIsolationForest fails when maxfeatures is less than 1 5732 by Ishank Gulati
- Fix a bug where gradient boosting with lossquantile computed negative errors for negative values of ytrue ypred leading to wrong values when calling call 8087 by Alexis Mignon
- Fix a bug where ensembleVotingClassifier raises an error when a numpy array is passed in for weights 7983 by Vincent Pham
- Fixed a bug where treeexportgraphviz raised an error when the length of featuresnames does not match nfeatures in the decision tree 8512 by Li Li

Linear kernelized and related models

- Fixed a bug where linearmodelRANSACRegressororfit may run until maxiter if it finds a large inlier group early 8251 by aivision2020
- Fixed a bug where naivebayesMultinomialNB andnaivebayesBernoulliNB failed when alpha0 5814 by Yichuan Liu and Herilalaina Rakotoarison

scikitlearn user guide Release 0213

- Fixed a bug where linearmodelLassoLars does not give the same result as the LassoLars implementation available in R lars library 7849 by Jair Montoya Martinez
 - Fixed a bug in linearmodelRandomizedLasso linearmodelLars linearmodelLassoLars linearmodelLarsCV andlinearmodelLassoLarsCV where the parameter precompute was not used consistently across classes and some values proposed in the docstring could raise errors 5359 by Tom Dupre la Tour
 - Fix inconsistent results between linearmodelRidgeCV andlinearmodelRidge when using normalizeTrue 9302 by Alexandre Gramfort
 - Fix a bug where linearmodelLassoLarsfit sometimes left coef as a list rather than an ndarray 8160 by CJ Carey
 - FixlinearmodelBayesianRidgefit to return ridge parameter alpha andlambda consistent with calculated coefficients coef andintercept 8224 by Peter Gedeck
 - Fixed a bug in svmOneClassSVM where it returned floats instead of integer classes 8676 by Vathsala Achar
 - Fix AICBIC criterion computation in linearmodelLassoLarsIC 9022 by Alexandre Gramfort and Mehmet Basbug
 - Fixed a memory leak in our LibLinear implementation 9024 by Sergei Lebedev
 - Fix bug where stratified CV (Cross-Validation) splitters did not work with linearmodelLassoCV 8973 by Paulo Haddad
 - Fixed a bug in gaussianprocessGaussianProcessRegressor when the standard deviation and covariance predicted without fit would fail with a unmeaningful error by default 6573 by Quazi Marufur Rahman and Manoj Kumar
- Other predictors
- FixsemisupervisedBaseLabelPropagation to correctly implement LabelPropagation and LabelSpreading as done in the referenced papers 9239 by Andre Ambrosio Boechat Utkarsh Upadhyay and Joel Nothman
- Decomposition manifold learning and clustering
- Fixed the implementation of manifoldTSNE
 - earlyexageration parameter had no effect and is now used for the first 250 optimization iterations
 - Fixed the AssertionError Tree consistency failed exception reported in 8992
 - Improve the learning schedule to match the one from the reference implementation lvdmaatenbhtsne by Thomas Moreau and Olivier Grisel
 - Fix a bug in decompositionLatentDirichletAllocation where theperplexity method was returning incorrect results because the transform method returns normalized document topic distributions as of version 018 7954 by Gary Foreman
 - Fix output shape and bugs with njobs 1 in decompositionSparseCoder transform and decompositionsparsencode for onedimensional data and one component This also impacts the output shape of decompositionDictionaryLearning 8086 by Andreas Müller
 - Fixed the implementation of explainedvariance indecompositionPCA decomposition RandomizedPCA anddecompositionIncrementalPCA 9105 by Hanmin Qin
 - Fixed the implementation of noisevariance indecompositionPCA 9108 by Hanmin Qin
 - Fixed a bug where clusterDBSCAN gives incorrect result when input is a precomputed sparse matrix with initial rows all zero 8306 by Akshay Gupta
- 117 Previous Releases 71

scikitlearn user guide Release 0213

- Fix a bug regarding fitting clusterKMeans with a sparse array X and initial centroids where X’s means were unnecessarily being subtracted from the centroids 7872 by Josh Karnofsky
- Fixes to the input validation in covarianceEllipticEnvelope 8086 by Andreas Müller
- Fixed a bug in covarianceMinCovDet where inputting data that produced a singular covariance matrix would cause the helper method cstep to throw an exception 3367 by Jeremy Steward
- Fixed a bug in manifoldTSNE affecting convergence of the gradient descent 8768 by David DeTomaso
- Fixed a bug in manifoldTSNE where it stored the incorrect kldivergence 6507 by Sebastian Saeger
- Fixed improper scaling in crossdecompositionPLSRegression withscaleTrue 7819 by jayzed82
- clusterbiclusterSpectralCoclustering and clusterbiclusterSpectralBiclustering fit method conforms with API (Application Programming Interface) by accepting yand returning the object 6126 7814 by Laurent Direr and Maniteja Nandana
- Fix bug where mixturesample methods did not return as many samples as requested 7702 by Levi John Wolf
- Fixed the shrinkage implementation in neighborsNearestCentroid 9219 by Hanmin Qin
- Preprocessing and feature selection
 - For sparse matrices preprocessingnormalize withreturnnormTrue will now raise a NotImplementedError with ‘l1’ or ‘l2’ norm and with norm ‘max’ the norms returned will be the same as for dense matrices 7771 by Ang Lu
 - Fix a bug where featuresselectionSelectFdr did not exactly implement BenjaminiHochberg procedure It formerly may have selected fewer features than it should 7490 by Peng Meng
 - Fixed a bug where linearmodelRandomizedLasso andlinearmodelRandomizedLogisticRegression breaks for sparse input 8259 by Aman Dalmia
 - Fix a bug where featureextractionFeatureHasher mandatorily applied a sparse random projection to the hashed features preventing the use of featureextractiontextHashingVectorizer in a pipeline with featureextractiontextTfidfTransformer 7565 by Roman Yurchak
 - Fix a bug where featuresselectionmutualinfo regression did not correctly use nneighbors 8181 by Guillaume Lemaitre
- Model evaluation and metaestimators
 - Fixed a bug where modelselectionBaseSearchCVinversetransform returnsselfbestestimatortransform instead of selfbestestimatorinversetransform 8344 by Akshay Gupta and Rasmus Eriksson
 - Added classes attribute to modelselectionGridSearchCV modelselectionRandomizedSearchCV gridsearchGridSearchCV and gridsearchRandomizedSearchCV that matches the classes attribute of bestestimator 7661 and 8295 by Alyssa Batula Dylan WernerMeier and Stephen Hoover
 - Fixed a bug where modelselectionvalidationcurve reused the same estimator for each parameter value 7365 by Aleksandr Sandrovskii
 - modelselectionpermutationtestscore now works with Pandas types 5697 by Stijn Tonk
 - Several fixes to input validation in multiclassOutputCodeClassifier 8086 by Andreas Müller
 - multiclassOneVsOneClassifier ‘spartialfit now ensures all classes are provided upfront 6250 by Asish Panda

scikitlearn user guide Release 0213

- FixmultioutputMultiOutputClassifierpredictproba to return a list of 2d arrays rather than a 3d array In the case where different target columns had different numbers of classes a ValueError would be raised on trying to stack matrices with different dimensions 8093 by Peter Bull
 - Cross validation now works with Pandas datatypes that that have a readonly index 9507 by Loic Esteve Metrics
 - metricsaverageprecisionscore no longer linearly interpolates between operating points and in stead weighs precisions by the change in recall since the last operating point as per the Wikipedia entry 7356 By Nick Dingwall and Gael Varoquaux
 - Fix a bug in metricsclassificationchecktargets which would return binary ifytrue andypred were bothbinary but the union of ytrue andypred wasmulticlass 8377 by Loic Esteve
 - Fixed an integer overflow bug in metricsconfusionmatrix and hence metrics cohenkappascore 8354 7929 by Joel Nothman and Jon Crall
 - Fixed passing of gamma parameter to the chi2 kernel inmetricspairwisepairwise kernels 5211 by Nick Rhinehart Saurabh Bansod and Andreas Müller
- Miscellaneous
- Fixed a bug when datasetsmakeclassification fails when generating more than 30 features 8159 by Herilalaina Rakotoarison
 - Fixed a bug where datasetsmakemoons gives an incorrect result when nsamples is odd 8198 by Josh Levy
 - Somefetch functions in datasets were ignoring the downloadifmissing keyword 7944 by Ralf Gommers
 - Fix estimators to accept a sampleweight parameter of type pandasSeries in theirfit function 7825 by Kathleen Chen
 - Fix a bug in cases where numpycumsum may be numerically unstable raising an exception if instability is identified 7376 and 7331 by Joel Nothman and yangarbiter
 - Fix a bug where baseBaseEstimatorgetstate obstructed pickling customizations of child classes when used in a multiple inheritance context 8316 by Holger Peters
 - Update SphinxGallery from 014 to 017 for resolving links in documentation build with Sphinx15 8010 7986 by Oscar Najera
 - Adddatahome parameter to sklearndatasetsfetchkddcup99 9289 by Loic Esteve
 - Fix dataset loaders using Python 3 version of makedirs to also work in Python 2 9284 by Sebastin Santy
 - Several minor issues were fixed with thanks to the alerts of lgtmcomhttpslgtmcom 9278 by Jean Helie among others

API (Application Programming Interface) changes summary

Trees and ensembles

- Gradient boosting base models are no longer estimators By Andreas Müller
- All tree based estimators now accept a minimpuritydecrease parameter in lieu of the minimpuritysplit which is now deprecated The minimpuritydecrease helps stop splitting the nodes in which the weighted impurity decrease from splitting is no longer at least minimpuritydecrease 8449 by Raghav RV 117 Previous Releases 73

scikitlearn user guide Release 0213

Linear kernelized and related models

- niter parameter is deprecated in linearmodelSGDClassifier linearmodelSGDRegressor linearmodelPassiveAggressiveClassifier linearmodelPassiveAggressiveRegressor and linearmodelPerceptron By Tom Dupre la Tour
- Other predictors

• neighborsLSHForest has been deprecated and will be removed in 021 due to poor performance 9078 by Laurent Direr

• neighborsNearestCentroid no longer purports to support metricprecomputed which now raises an error 8515 by Sergul Aydore

• Thealpha parameter of semisupervisedLabelPropagation now has no effect and is deprecated to be removed in 021 9239 by Andre Ambrosio Boechat Utkarsh Upadhyay and Joel Nothman

Decomposition manifold learning and clustering

- Deprecate the doctopicdistr argument of the perplexity method in decompositionLatentDirichletAllocation because the user no longer has access to the unnormalized document topic distribution needed for the perplexity calculation 7954 by Gary Foreman

- Thentopics parameter of decompositionLatentDirichletAllocation has been renamed to ncomponents and will be removed in version 021 8922 by Attractadore

- decompositionSparsePCATransform 'sridgealpha parameter is deprecated in preference for class parameter 8137 by Naoya Kanai

- clusterDBSCAN now has ametricparams parameter 8139 by Naoya Kanai

Preprocessing and feature selection

- featureselectionSelectFromModel now has a partialfit method only if the underlying estimator does By Andreas Müller

- featureselectionSelectFromModel now validates the threshold parameter and sets the threshold attribute during the call to fit and no longer during the call to transform By Andreas Müller

- Thenonnegative parameter in featureextractionFeatureHasher has been deprecated and replaced with a more principled alternative alternatesign 7565 by Roman Yurchak

- linearmodelRandomizedLogisticRegression and linearmodelRandomizedLasso have been deprecated and will be removed in version 021 8995 by RamanaS

Model evaluation and metaestimators

- Deprecate the fitparams constructor input to the modelselectionGridSearchCV and modelselectionRandomizedSearchCV in favor of passing keyword parameters to the fit methods

of those classes Data dependent parameters needed for model training should be passed as keyword arguments to fit and conforming to this convention will allow the hyperparameter selection classes to be used with tools such as modelselectioncrossvalpredict 2879 by Stephen Hoover

- In version 021 the default behavior of splitters that use the testsize and trainsize parameter will change such that specifying trainsize alone will cause testsize to be the remainder 7459 by Nelson Liu

- multiclassOneVsRestClassifier now has partialfit decisionfunction and predict_proba methods only when the underlying estimator does 7812 by Andreas Müller and Mikhail Korobov

- multiclassOneVsRestClassifier now has a partialfit method only if the underlying estimator does By Andreas Müller

scikitlearn user guide Release 0213

- The decision function output shape for binary classification in multiclass OneVsRestClassifier and multiclass OneVsOneClassifier is now n_samples to conform to scikitlearn conventions 9100 by Andreas Müller
 - The multioutput MultiOutputClassifier.predict_proba function used to return a 3d array n_samples n_classes n_outputs. In the case where different target columns had different numbers of classes a ValueError would be raised on trying to stack matrices with different dimensions. This function now returns a list of arrays where the length of the list is n_outputs and each array is n_samples n_classes for that particular output 8093 by Peter Bull
 - Replace attribute named_steps dict to utils.Bunch in pipeline Pipeline to enable tab completion in interactive environment. In the case of conflict value on named_steps and dict attribute dict behavior will be prioritized 8481 by Herilalaina Rakotoarison
- Miscellaneous
- Deprecate the y parameter in transform and inverse_transform. The method should not accept y parameter as it's used at the prediction time 8174 by Tahar Zanouda, Alexandre Gramfort and Raghav RV
 - SciPy 0.13.3 and NumPy 1.8.2 are now the minimum supported versions for scikitlearn. The following backported functions in utils have been removed or deprecated accordingly 8854 and 8874 by Naoya Kanai

- The store_covariances and covariances parameters of discriminant analysis QuadraticDiscriminantAnalysis has been renamed to store_covariance and covariance to be consistent with the corresponding parameter names of the discriminant analysis LinearDiscriminantAnalysis. They will be removed in version 0.21 7998 by Jiacheng

Removed in 0.19

- utils.fixes.argmaxpartition
- utils.fixes.array_equal
- utils.fixes.astype
- utils.fixes.bincount
- utils.fixes.expit
- utils.fixes.frombufferempty
- utils.fixes.in1d
- utils.fixes.norm
- utils.fixes.rankdata
- utils.fixes.safe_copy

Deprecated in 0.19 to be removed in 0.21

- utils.srpackeigs
- utils.srpackeigsh
- utils.srpacksvds
- utils.srpackfastdot
- utils.srpacklogsumexp
- utils.srpacknorm
- utils.srpackpinvh
- utils.graphgraphlaplacian

117 Previous Releases 75

scikitlearn user guide Release 0213

-utilsrandomchoice

-utilssparsetoolsconnectedcomponents

-utilsstatsrankdata

- Estimators with both methods decisionfunction andpredictproba are now required to have a monotonic relation between them The method checkdecisionprobaconsistency has been added inutilessestimatorchecks to check their consistency 7578 by Shubham Bhardwaj

- All checks in utilsestimatorchecks in particular utilsestimatorchecks

checkestimator now accept estimator instances Most other checks do not accept estimator classes any more 9019 by Andreas Müller

- Ensure that estimators’ attributes ending with are not set in the constructor but only in the fit method Most notably ensemble estimators deriving from ensembleBaseEnsemble now only have self estimators available after fit 7464 by Lars Buitinck and Loic Esteve

Code and Documentation Contributors

1174 Version 0182

June 20 2017

Last release with Python 26 support

Scikitlearn 018 is the last major release of scikitlearn to support Python 26 Later versions of scikitlearn will
require Python 27 or above

Changelog

- Fixes for compatibility with NumPy 1130 7946 8355 by Loic Esteve
- Minor compatibility changes in the examples 9010 8040 9149

Code Contributors

Aman Dalmia Loic Esteve Nate Guerin Sergei Lebedev

1175 Version 0181

November 11 2016

Changelog

Enhancements

- Improved samplewithoutreplacement speed by utilizing numpyrandompermutation for most cases

As a result samples may differ in this release for a fixed random state Affected estimators

-ensembleBaggingClassifier

-ensembleBaggingRegressor

-linearmodelRANSACRegressor

-modelselectionRandomizedSearchCV

-randomprojectionSparseRandomProjection

This also affects the datasetsmakeclassification method

117 Previous Releases 77

scikitlearn user guide Release 0213

Bug fixes

- Fix issue where mingradnorm andniterwithoutprogress parameters were not being utilised bymanifoldTSNE 6497 by Sebastian Säger
 - Fix bug for svm’s decision values when decisionfunctionshape isovr insvmSVC svmSVC ’s decisionfunction was incorrect from versions 0170 through 0180 7724 by Bing Tian Dai
 - Attribute explainedvarianceratio of discriminantanalysis LinearDiscriminantAnalysis calculated with SVD and Eigen solver are now of the same length 7632 by JPFrancoia
 - Fixes issue in Univariate feature selection where score functions were not accepting multilabel targets 7676 by Mohammed Affan
 - Fixed setting parameters when calling fit multiple times on featureselectionSelectFromModel 7756 by Andreas Müller
 - Fixes issue in partialfit method ofmulticlassOneVsRestClassifier when number of classes used inpartialfit was less than the total number of classes in the data 7786 by Srivatsan Ramesh
 - Fixes issue in calibrationCalibratedClassifierCV where the sum of probabilities of each class for a data was not 1 and CalibratedClassifierCV now handles the case where the training set has less number of classes than the total data 7799 by Srivatsan Ramesh
 - Fix a bug where sklearnfeatureselectionSelectFdr did not exactly implement Benjamini Hochberg procedure It formerly may have selected fewer features than it should 7490 by Peng Meng
 - sklearnmanifoldLocallyLinearEmbedding now correctly handles integer inputs 6282 by Jake Vanderplas
 - Them inweightfractionleaf parameter of treebased classifiers and regressors now assumes uniform sample weights by default if the sampleweight argument is not passed to the fit function Previously the parameter was silently ignored 7301 by Nelson Liu
 - Numerical issue with linearmodelRidgeCV on centered data when nfeatures nsamples 6178 by Bertrand Thirion
 - Tree splitting criterion classes’ cloningpickling is now memory safe 7680 by Ibraim Ganiev
 - Fixed a bug where decompositionNMF sets itsnitters attribute in transform 7553 by Ekaterina Krivich
 - sklearnlinearmodelLogisticRegressionCV now correctly handles string labels 5874 by Raghav RV
 - Fixed a bug where sklearnmodelselectiontraintestsplit raised an error when stratify is a list of string labels 7593 by Raghav RV
 - Fixed a bug where sklearnmodelselectionGridSearchCV andsklearn modelselectionRandomizedSearchCV were not pickleable because of a pickling bug in np.maMaskedArray 7594 by Raghav RV
 - All crossvalidation utilities in sklearnmodelselection now permit one time crossvalidation splitters for thecvparameter Also nondeterministic crossvalidation splitters where multiple calls to split produce dissimilar splits can be used as cvparameter The sklearnmodelselectionGridSearchCV will crossvalidate each parameter setting on the split produced by the first split call to the crossvalidation splitter 7660 by Raghav RV
 - Fix bug where preprocessingMultiLabelBinarizerfittransform returned an invalid CSR (Compressed Sparse Row) matrix 7750 by CJ Carey
- 78 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Fixed a bug where metricspairwisecosinedistances could return a small negative distance 7732 by Artsion

API (Application Programming Interface) changes summary

Trees and forests

- The minweightfractionleaf parameter of treebased classifiers and regressors now assumes uniform sample weights by default if the sampleweight argument is not passed to the fit function Previously the parameter was silently ignored 7301 by Nelson Liu
- Tree splitting criterion classes' cloningpickling is now memory safe 7680 by Ibraim Ganiev

Linear kernelized and related models

- Length of explainedvarianceratio ofdiscriminantanalysis LinearDiscriminantAnalysis changed for both Eigen and SVD solvers The attribute has now a length of minncomponents nclasses 1 7632 by JPFrancoia
- Numerical issue with linearmodelRidgeCV on centered data when nfeatures nsamples 6178 by Bertrand Thirion

1176 Version 018

September 28 2016

Last release with Python 26 support

Scikitlearn 018 will be the last version of scikitlearn to support Python 26 Later versions of scikitlearn will require Python 27 or above

Model Selection Enhancements and API (Application Programming Interface) Changes

- The modelselection module

The new module sklearnmodelselection which groups together the functionalities of formerly sklearncrossvalidation sklearngridsearch andsklearnlearningcurve introduces new possibilities such as nested crossvalidation and better manipulation of parameter searches with Pandas

Many things will stay the same but there are some key differences Read below to know more about the changes

- Dataindependent CV (Cross-Validation) splitters enabling nested crossvalidation

The new crossvalidation splitters defined in the sklearnmodelselection are no longer initialized with any datadependent parameters such as y Instead they expose a split method that takes in the data and yields a generator for the different splits

This change makes it possible to use the crossvalidation splitters to perform nested crossvalidation facilitated bymodelselectionGridSearchCV andmodelselectionRandomizedSearchCV utilities

- The enhanced cvresults attribute

The newcvresults attribute of modelselectionGridSearchCV andmodelselection RandomizedSearchCV introduced in lieu of the gridscores attribute is a dict of 1D arrays with elements in each array corresponding to the parameter settings ie search candidates

117 Previous Releases 79

scikitlearn user guide Release 0213

Thecvresults dict can be easily imported into pandas as aDataFrame for exploring the search results

Thecvresults arrays include scores for each crossvalidation split with keys such as

split0testscore as well as their mean meantestscore and standard deviation

stdtestscore

The ranks for the search candidates based on their mean crossvalidation score is available at

cvresultsranktestscore

The parameter values for each parameter is stored separately as numpy masked object arrays The value for

that search candidate is masked if the corresponding parameter is not applicable Additionally a list of all the

parameter dicts are stored at cvresultsparams

•Parameters nfolds and niter renamed to nsplits

Some parameter names have changed The nfolds parameter in new modelselectionKFold

modelselectionGroupKFold see below for the name change and modelselection

StratifiedKFold is now renamed to nsplits Theniter parameter in modelselection

ShuffleSplit the new class modelselectionGroupShuffleSplit andmodelselection

StratifiedShuffleSplit is now renamed to nsplits

•Rename of splitter classes which accepts group labels along with data

The crossvalidation splitters LabelKFold LabelShuffleSplit LeaveOneLabelOut and

LeavePLabelOut have been renamed to modelselectionGroupKFold modelselection

GroupShuffleSplit modelselectionLeaveOneGroupOut andmodelselection

LeavePGroupsOut respectively

Note the change from singular form to plural form in modelselectionLeavePGroupsOut

•Fit parameter labels renamed to groups

Thelabels parameter in the split method of the newly renamed splitters modelselection

GroupKFold modelselectionLeaveOneGroupOut modelselection

LeavePGroupsOut modelselectionGroupShuffleSplit is renamed to groups following the

new nomenclature of their class names

•Parameter nlabels renamed to ngroups

The parameter nlabels in the newly renamed modelselectionLeavePGroupsOut is changed to

ngroups

• Training scores and Timing information

cvresults also includes the training scores for each crossvalidation split with keys such

assplit0trainscore as well as their mean meantrainscore and stan

dard deviation stdtrainscore To avoid the cost of evaluating training score set

returntrainscoreFalse

Additionally the mean and standard deviation of the times taken to split train and score the model across all the

crossvalidation splits is available at the key meantime andstdtime respectively

Changelog

New features

Classifiers and Regressors

• The Gaussian Process module has been reimplemented and now offers classification and regression esti

matoms through gaussianprocessGaussianProcessClassifier andgaussianprocess

GaussianProcessRegressor Among other things the new implementation supports kernel engineering

80 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

gradientbased hyperparameter optimization or sampling of functions from GP prior and GP posterior Extensive documentation and examples are provided By Jan Hendrik Metzen

- Added new supervised learning algorithm Multilayer Perceptron 3204 by Issam H Laradji
- AddedlinearmodelHuberRegressor a linear model robust to outliers 5291 by Manoj Kumar
- Added the multioutputMultiOutputRegressor metaestimator It converts single output regressors to multioutput regressors by fitting one regressor per output By Tim Head

Other estimators

- NewmixtureGaussianMixture andmixtureBayesianGaussianMixture replace former mixture models employing faster inference for sounder results 7295 by Wei Xue and Thierry Guillemot
- ClassdecompositionRandomizedPCA is now factored into decompositionPCA and it is available calling with parameter svdsolverrandomized The default number of niter for randomized has changed to 4 The old behavior of PCA (Principal Component Analysis) is recovered by svdsolverfull An additional solver calls arpack and performs truncated nonrandomized SVD By default the best solver is selected depending on the size of the input and the number of components requested 5299 by Giorgio Patrini
- Added two functions for mutual information estimation featuresselection mutualinfoclassif andfeaturesselectionmutualinfo regression These functions can be used in featuresselectionSelectKBest andfeaturesselectionSelectPercentile as score functions By Andrea Bravi and Nikolay Mayorov
- Added the ensembleIsolationForest class for anomaly detection based on random forests By Nicolas Goix

- Addedalgorithmelkan toclusterKMeans implementing Elkan’s fast KMeans algorithm By Andreas Müller

Model selection and evaluation

- Addedmetricsclusterfowlkesmallowsscore the Fowlkes Mallows Index which measures the similarity of two clusterings of a set of points By Arnaud Fouchet and Thierry Guillemot
- Addedmetricscalinskiharabazscore which computes the Calinski and Harabaz score to evaluate the resulting clustering of a set of points By Arnaud Fouchet and Thierry Guillemot
- Added new crossvalidation splitter modelselectionTimeSeriesSplit to handle time series data 6586 by YenChen Lin
- The crossvalidation iterators are replaced by crossvalidation splitters available from sklearn modelselection allowing for nested crossvalidation See Model Selection Enhancements and API (Application Programming Interface) Changes for more information 4294 by Raghav RV

Enhancements

Trees and ensembles

- Added a new splitting criterion for treeDecisionTreeRegressor the mean absolute error This criterion can also be used in ensembleExtraTreesRegressor ensemble RandomForestRegressor and the gradient boosting estimators 6667 by Nelson Liu
- Added weighted impuritybased early stopping criterion for decision tree growth 6954 by Nelson Liu
- The random forest extra tree and decision tree estimators now has a method decisionpath which returns the decision path of samples in the tree By Arnaud Joly
- A new example has been added unveiling the decision tree structure By Arnaud Joly

scikitlearn user guide Release 0213

- Random forest extra trees decision trees and gradient boosting estimator accept the parameter minsamplesplit and minsamplesleaf provided as a percentage of the training samples By yelite and Arnaud Joly
 - Gradient boosting estimators accept the parameter criterion to specify to splitting criterion used in built decision trees 6667 by Nelson Liu
 - The memory footprint is reduced sometimes greatly for ensemblebaggingBaseBagging and classes that inherit from it ie ensembleBaggingClassifier ensembleBaggingRegressor and ensembleIsolationForest by dynamically generating attribute estimatorssamples only when it is needed By David Staub
 - Addednjobs andsampleweight parameters for ensembleVotingClassifier to fit underlying estimators in parallel 5805 by Ibraim Ganiev
 - Linear kernelized and related models
 - InlinearmodelLogisticRegression the SAG solver is now available in the multinomial case 5251 by Tom Dupre la Tour
 - linearmodelRANSACRegressor svmLinearSVC andsvmLinearSVR now support sampleweight By Imaculate
 - Add parameter loss tolinearmodelRANSACRegressor to measure the error on the samples for every trial By Manoj Kumar
 - Prediction of outofsample events with Isotonic Regression isotonicIsotonicRegression is now much faster over 1000x in tests with synthetic data By Jonathan Arfa
 - Isotonic regression isotonicIsotonicRegression now uses a better algorithm to avoid On2 behavior in pathological cases and is also generally faster 6691 By Antony Lee
 - naivebayesGaussianNB now accepts dataindependent classpriors through the parameter priors By Guillaume Lemaitre
 - linearmodelElasticNet andlinearmodelLasso now works with npfloat32 input data without converting it into npfloat64 This allows to reduce the memory consumption 6913 by YenChen Lin
 - semisupervisedLabelPropagation andsemisupervisedLabelSpreading now accept arbitrary kernel functions in addition to strings knn andrbf 5762 by Utkarsh Upadhyay
 - Decomposition manifold learning and clustering
 - Addedinversetransform function to decompositionNMF to compute data matrix of original shape By Anish Shah
 - clusterKMeans andclusterMiniBatchKMeans now works with npfloat32 andnp float64 input data without converting it This allows to reduce the memory consumption by using np float32 6846 by Sebastian Säger and YenChen Lin
 - Preprocessing and feature selection
 - preprocessingRobustScaler now accepts quantilerange parameter 5929 by Konstantin Pod shumok
 - featureextractionFeatureHasher now accepts string values 6173 by Ryad Zenine and Devashish Deshpande
 - Keyword arguments can now be supplied to func inpreprocessingFunctionTransformer by means of the kwargs parameter By Brian McFee
 - featureselectionSelectKBest andfeatureselectionSelectPercentile now accept score functions that take X y as input and return only the scores By Nikolay Mayorov
- 82 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

Model evaluation and metaestimators

- multiclassOneVsOneClassifier andmulticlassOneVsRestClassifier now support partialfit By Asish Panda and Philipp Dowling
- Added support for substituting or disabling pipelinePipeline andpipelineFeatureUnion components using the setparams interface that powers sklearngridsearch See Selecting dimensionality reduction with Pipeline and GridSearchCV By Joel Nothman and Robert McGibbon
- The new cvresults attribute of modelselectionGridSearchCV andmodelselectionRandomizedSearchCV can be easily imported into pandas as a DataFrame Ref Model Selection Enhancements and API (Application Programming Interface) Changes for more information 6697 by Raghav RV
- Generalization of modelselectioncrossvalpredict One can pass method names such as predictproba to be used in the cross validation framework instead of the default predict By Ori Ziv and Sears Merritt
- The training scores and time taken for training followed by scoring for each search candidate are now available at thecvresults dict See Model Selection Enhancements and API (Application Programming Interface) Changes for more information 7325 by Eugene Chen and Raghav RV

Metrics

- Addedlabels flag tometricslogloss to explicitly provide the labels when the number of classes in ytrue andypred differ 7239 by Hong Guangguo with help from Mads Jensen and Nelson Liu
- Support sparse contingency matrices in cluster evaluation metricsclustersupervised to scale to a large number of clusters 7419 by Gregory Stupp and Joel Nothman
- Addsampleweight parameter to metricsmatthewscorrcoef By Jatin Shah and Raghav RV
- Speed up metricssilhouettescore by using vectorized operations By Manoj Kumar
- Addsampleweight parameter to metricsconfusionmatrix By Bernardo Stein

Miscellaneous

- Addednjobs parameter to featureselectionRFECV to compute the score on the test folds in parallel By Manoj Kumar
- Codebase does not contain CC cython generated files they are generated during build Distribution packages will still contain generated CC files By Arthur Mensch
- Reduce the memory usage for 32bit float input arrays of utilssparsefuncmeanvarianceaxis andutilssparsefuncincrmearianceaxis by supporting cython fused types By YenChen Lin

- Theignorewarnings now accept a category argument to ignore only the warnings of a specified type By Thierry Guillemot

- Added parameter returnXy and return type data target tuple option toloadiris dataset 7049 loadbreastcancer dataset 7152 loaddigits datasetloaddiabetes dataset loadlinnerud datasetloadboston dataset 7154 by Manvendra Singh

- Simplification of the clone function deprecate support for estimators that modify parameters in init 5540 by Andreas Müller
- When unpickling a scikitlearn estimator in a different version than the one the estimator was trained with a UserWarning is raised see the documentation on model persistence for more details 7248 By Andreas Müller

scikitlearn user guide Release 0213

Bug fixes

Trees and ensembles

- Random forest extra trees decision trees and gradient boosting won't accept anymore `minsampleleavesplit=1` as at least 2 samples are required to split a decision tree node By Arnaud Joly

- `ensembleVotingClassifier` now raises `NotFittedError` if `predict` transform or `predict_proba` are called on the nonfitted estimator by Sebastian Raschka
- Fix bug where `ensembleAdaBoostClassifier` and `ensembleAdaBoostRegressor` would perform poorly if the `randomstate` was fixed 7411 By Joel Nothman
- Fix bug in ensembles with randomization where the ensemble would not set `randomstate` on base estimators in a pipeline or similar nesting 7411 Note results for `ensembleBaggingClassifier` `ensembleBaggingRegressor` `ensembleAdaBoostClassifier` and `ensembleAdaBoostRegressor` will now differ from previous versions By Joel Nothman

Linear kernelized and related models

- Fixed incorrect gradient computation for `losssquaredepsiloninsensitive` in `linearmodelSGDClassifier` and `linearmodelSGDRegressor` 6764 By Wenhua Yang

- Fix bug in `linearmodelLogisticRegressionCV` where `resolverliblinear` did not accept `classweightsbalanced` 6817 By Tom Dupre la Tour

- Fix bug in `neighborsRadiusNeighborsClassifier` where an error occurred when there were outliers being labelled and a weight function specified 6902 By LeonieBorne
- Fix `linearmodelElasticNet` sparse decision function to match output with dense in the multioutput case

Decomposition manifold learning and clustering

- `decompositionRandomizedPCA` default number of iterations `power` is 4 instead of 3 5141 by

Giorgio Patrini

- `utilsextramatrandomizedsvd` performs 4 power iterations by default instead of 0 In practice this is enough for obtaining a good approximation of the true eigenvalues/vectors in the presence of noise When `ncomponents` is small `1/min(X.shape[0], X.shape[1])` `niter` is set to 7 unless the user specifies a higher number This improves precision with few components 5299 by Giorgio Patrini

- `WhitenNonWhiten` inconsistency between components of `decompositionPCA` and `decompositionRandomizedPCA` now factored into `PCA` (Principal Component Analysis) see the `New features` is fixed components are stored with no whitening 5299 by Giorgio Patrini

- Fixed bug in `manifoldspectralembedding` where diagonal of unnormalized Laplacian matrix was incorrectly set to 1 4995 by Peter Fischer

- Fixed incorrect initialization of `utils.sparsepack.eigsh` on all occurrences Affects `cluster_bicluster_spectral` `biclustering` `decompositionKernelPCA` `manifoldLocallyLinearEmbedding` and `manifoldSpectralEmbedding` 5012 By Peter Fischer

- `Attribute explained_variance_ratio` calculated with the SVD solver of `discriminantanalysis.LinearDiscriminantAnalysis` now returns correct results By JPFrancoia

Preprocessing and feature selection

- `preprocessing.data_transform_selected` now always passes a copy of `X` to transform function when `copy=True` 7194 By Caio Oliveira

scikitlearn user guide Release 0213

Model evaluation and metaestimators

- modelselectionStratifiedKFold now raises error if all nlabels for individual classes is less than nfolds 6182 by Devashish Deshpande
- Fixed bug in modelselectionStratifiedShuffleSplit where train and test sample could overlap in some edge cases see 6121 for more details By Loic Esteve
- Fix in sklearnmodelselectionStratifiedShuffleSplit to return splits of size trainsize andtestsize in all cases 6472 By Andreas Müller
- Crossvalidation of OneVsOneClassifier andOneVsRestClassifier now works with precomputed kernels 7350 by Russell Smith
- Fix incomplete predictproba method delegation from modelselectionGridSearchCV to linearmodelSGDClassifier 7159 by Yichuan Liu

Metrics

- Fix bug in metricssilhouettescore in which clusters of size 1 were incorrectly scored They should get a score of 0 By Joel Nothman
- Fix bug in metricssilhouettesamples so that it now works with arbitrary labels not just those ranging from 0 to nclusters 1
- Fix bug where expected and adjusted mutual information were incorrect if cluster contingency cells exceeded 216 By Joel Nothman
- metricspairwisepairwisedistances now converts arrays to boolean arrays when required in scipyspatialdistance 5460 by Tom Dupre la Tour
- Fix sparse input support in metricssilhouettescore as well as example exam
- plestextdocumentclusteringpy By YenChen Lin
- metricsroccurve andmetricsprecisionrecallcurve no longer round yscore values when creating ROC curves this was causing problems for users with very small differences in scores 7353

Miscellaneous

- modelselectiontestsearchcheckparamgrid now works correctly with all types that extendsimplements Sequence except string including range Python 3x and xrange Python 2x 7323 by Viacheslav Kovalevskyi
 - utilsextmathrandomizedrangefinder is more numerically stable when many power iterations are requested since it applies LU normalization by default If niter2 numerical issues are unlikely thus no normalization is applied Other normalization options are available none LU andQR 5141 by Giorgio Patrini
 - Fix a bug where some formats of scipysparse matrix and estimators with them as parameters could not be passed to baseclone By Loic Esteve
 - datasetsloadsvmlightfile now is able to read long int QID values 7101 by Ibraim Ganiev
- API (Application Programming Interface) changes summary
- Linear kernelized and related models
- residualmetric has been deprecated in linearmodelIRANSACRegressor Use loss instead
- By Manoj Kumar
- Access to public attributes X and y has been deprecated in isotonicIsotonicRegression By Jonathan Arfa

scikitlearn user guide Release 0213

Decomposition manifold learning and clustering

- The oldmixtureDPGMM is deprecated in favor of the new mixtureBayesianGaussianMixture with the parameter weightconcentrationpriortypedirichletprocess The new class solves the computational problems of the old class and computes the Gaussian mixture with a Dirichlet process prior faster than before 7295 by Wei Xue and Thierry Guillemot
- The oldmixtureVBGMM is deprecated in favor of the new mixtureBayesianGaussianMixture with the parameter weightconcentrationpriortypedirichletdistribution The new class solves the computational problems of the old class and computes the Variational Bayesian Gaussian mixture faster than before 6651 by Wei Xue and Thierry Guillemot
- The oldmixtureGMM is deprecated in favor of the new mixtureGaussianMixture The new class computes the Gaussian mixture faster than before and some of computational problems have been solved 6666 by Wei Xue and Thierry Guillemot

Model evaluation and metaestimators

- Thesklearncrossvalidation sklearngridsearch andsklearnlearningcurve have been deprecated and the classes and functions have been reorganized into the sklearn modelselection module Ref Model Selection Enhancements and API (Application Programming Interface) Changes for more information 4294 by Raghav RV
- Thegridscores attribute of modelselectionGridSearchCV andmodelselection RandomizedSearchCV is deprecated in favor of the attribute cvresults Ref Model Selection Enhancements and API (Application Programming Interface) Changes for more information 6697 by Raghav RV
- The parameters niter ornolds in old CV (Cross-Validation) splitters are replaced by the new parameter nsplits since it can provide a consistent and unambiguous interface to represent the number of traintest splits 7187 by YenChen Lin
- classes parameter was renamed to labels inmetricshammingloss 7260 by Sebastián Vanrell
- The splitter classes LabelKFold LabelShuffleSplit LeaveOneLabelOut and LeavePLabelsOut are renamed to modelselectionGroupKFold modelselection GroupShuffleSplit modelselectionLeaveOneGroupOut andmodelselection LeavePGroupsOut respectively Also the parameter labels in thesplit method of the newly renamed splittersmodelselectionLeaveOneGroupOut andmodelselectionLeavePGroupsOut is renamed to groups Additionally in modelselectionLeavePGroupsOut the parameter nlabels is renamed to ngroups 6660 by Raghav RV
- Error and loss names for scoring parameters are now prefixed by neg such as negmeansquarederror The unprefixed versions are deprecated and will be removed in version 020 7261 by Tim Head

1177 Version 0171

February 18 2016

Changelog

Bug fixes

- Upgrade vendored joblib to version 094 that fixes an important bug in joblibParallel that can silently yield to wrong results when working on datasets larger than 1MB <https://github.com/joblib/joblib/blob/094>

CHANGESrst

- Fixed reading of Bunch pickles generated with scikitlearn version 016 This can affect users who have already downloaded a dataset with scikitlearn 016 and are loading it with scikitlearn 017 See 6196 for how this affected datasetsfetch20newsgroups By Loic Esteve

- Fixed a bug that prevented using ROC AUC score to perform grid search on several CPU cores on large arrays See 6147 By Olivier Grisel

- Fixed a bug that prevented to properly set the presort parameter in ensemble GradientBoostingRegressor See 5857 By Andrew McCulloh

- Fixed a joblib error when evaluating the perplexity of a decomposition LatentDirichletAllocation model See 6258 By ChyiKwei Yau

scikitlearn user guide Release 0213

1178 Version 017

November 5 2015

Changelog

New features

- All the Scaler classes but preprocessingRobustScaler can be fitted online by calling partialfit By Giorgio Patrini
 - The new class ensembleVotingClassifier implements a “majority rule” “soft voting” ensemble classifier to combine estimators for classification By Sebastian Raschka
 - The new class preprocessingRobustScaler provides an alternative to preprocessingStandardScaler for featurewise centering and range normalization that is robust to outliers By Thomas Unterthiner
 - The new class preprocessingMaxAbsScaler provides an alternative to preprocessingMinMaxScaler for featurewise range normalization when the data is already centered or sparse By Thomas Unterthiner
 - The new class preprocessingFunctionTransformer turns a Python function into a Pipeline compatible transformer object By Joe Jevnik
 - The new classes crossvalidationLabelKFold andcrossvalidationLabelShuffleSplit generate traintest folds respectively similar to crossvalidationKFold and crossvalidationShuffleSplit except that the folds are conditioned on a label array By Brian McFee Jean Kossaifi and Gilles Louppe
 - decompositionLatentDirichletAllocation implements the Latent Dirichlet Allocation topic model with online variational inference By ChyiKwei Yau with code based on an implementation by Matt Hoffman 3659
 - The new solver sag implements a Stochastic Average Gradient descent and is available in both linearmodelLogisticRegression andlinearmodelRidge This solver is very efficient for large datasets By Danny Sullivan and Tom Dupre la Tour 4738
 - The new solver cdimplements a Coordinate Descent in decompositionNMF Previous solver based on Projected Gradient is still available setting new parameter solver topg but is deprecated and will be removed in 019 along with decompositionProjectedGradientNMF and parameters sparseness eta beta andnlsmxiter New parameters alpha andl1ratio control L1 and L2 regularization and shuffle adds a shuffling step in the cdsolver By Tom Dupre la Tour and Mathieu Blondel
- Enhancements
- manifoldTSNE now supports approximate optimization via the BarnesHut method leading to much faster fitting By Christopher Erick Moody 4025
 - clustermeanshiftMeanShift now supports parallel execution as implemented in the meanshift function By Martino Sorbaro
 - naivebayesGaussianNB now supports fitting with sampleweight By Jan Hendrik Metzen
 - dummyDummyClassifier now supports a prior fitting strategy By Arnaud Joly
 - Added afitpredict method for mixtureGMM and subclasses By Cory Lorenz

88 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Added the metricslabelrankingloss metric By Arnaud Joly
- Added the metricscohenkappascore metric
- Added a warmstart constructor parameter to the bagging ensemble models to increase the size of the ensemble By Tim Head
- Added option to use multioutput regression metrics without averaging By Konstantin Shmelkov and Michael Eickenberg
- Addedstratify option tocrossvalidationtraintestsplit for stratified splitting By Miroslav Batchkarov
- Thetreeexportgraphviz function now supports aesthetic improvements for tree DecisionTreeClassifier andtreeDecisionTreeRegressor including options for coloring nodes by their majority class or impurity showing variable names and using node proportions instead of raw sample counts By Trevor Stephens
- Improved speed of newtoncg solver inlinearmodelLogisticRegression by avoiding loss computation By Mathieu Blondel and Tom Dupre la Tour
- Theclassweightauto heuristic in classifiers supporting classweight was deprecated and replaced by the classweightbalanced option which has a simpler formula and interpretation By Hanna Wallach and Andreas Müller
- Addclassweight parameter to automatically weight samples by class frequency for linearmodel PassiveAggressiveClassifier By Trevor Stephens
- Added backlinks from the API (Application Programming Interface) reference pages to the user guide By Andreas Müller
- Thelabels parameter to sklearnmetricsf1score sklearnmetricsfbetascore sklearnmetricsrecallscore andsklearnmetricsprecisionscore has been extended It is now possible to ignore one or more labels such as where a multiclass problem has a majority class to ignore By Joel Nothman
- Addsampleweight support tolinearmodelRidgeClassifier By Trevor Stephens
- Provide an option for sparse output from sklearnmetricspairwisecosinesimilarity By Jaidev Deshpande
- Addminmaxscale to provide a function interface for MinMaxScaler By Thomas Unterthiner
- dumpsvmlightfile now handles multilabel datasets By ChihWei Chang
- RCV1 dataset loader sklearndatasetsfetchrcv1 By Tom Dupre la Tour
- The “Wisconsin Breast Cancer” classical twoclass classification dataset is now included in scikitlearn available withsklearndatasetloadbreastcancer
- Upgraded to joblib 093 to benefit from the new automatic batching of short tasks This makes it possible for scikitlearn to benefit from parallelism when many very short tasks are executed in parallel for instance by the gridsearchGridSearchCV metaestimator with njobs 1 used with a large grid of parameters on a small dataset By Vlad Niculae Olivier Grisel and Loic Esteve
- For more details about changes in joblib 093 see the release notes <https://github.com/joblib/joblib/blob/master/CHANGESrstrelease093>
- Improved speed 3 times per iteration of decompositionDictLearning with coordinate descent method from linearmodelLasso By Arthur Mensch
- Parallel processing threaded for queries of nearest neighbors using the balltree by Nikolay Mayorov
- Allowdatasetmakemultilabelclassification to output a sparse y By Kashif Rasul

scikitlearn user guide Release 0213

- clusterDBSCAN now accepts a sparse matrix of precomputed distances allowing memoryefficient distance precomputation By Joel Nothman
 - treeDecisionTreeClassifier now exposes an apply method for retrieving the leaf indices samples are predicted as By Daniel Galvez and Gilles Louppe
 - Speed up decision tree regressors random forest regressors extra trees regressors and gradient boosting estimators by computing a proxy of the impurity improvement during the tree growth The proxy quantity is such that the split that maximizes this value also maximizes the impurity improvement By Arnaud Joly Jacob Schreiber and Gilles Louppe
 - Speed up tree based methods by reducing the number of computations needed when computing the impurity measure taking into account linear relationship of the computed statistics The effect is particularly visible with extra trees and on datasets with categorical or sparse features By Arnaud Joly
 - ensembleGradientBoostingRegressor andensembleGradientBoostingClassifier now expose an apply method for retrieving the leaf indices each sample ends up in under each try By Jacob Schreiber
 - Addsampleweight support tolinearmodelLinearRegression By Sonny Hu 4881
 - Addniterwithoutprogress tomanifoldTSNE to control the stopping criterion By Santi Vialba 5186
 - Added optional parameter randomstate inlinearmodelRidge to set the seed of the pseudo random generator used in sag solver By Tom Dupre la Tour
 - Added optional parameter warmstart inlinearmodelLogisticRegression If set to True the solverslbfgs newtoncg andsag will be initialized with the coefficients computed in the previous fit By Tom Dupre la Tour
 - Addedsampleweight support to linearmodelLogisticRegression for thelbfgs newtoncg andsag solvers By Valentin Stolbunov Support added to the liblinear solver By Manoj Kumar
 - Added optional parameter presort toensembleGradientBoostingRegressor andensemble GradientBoostingClassifier keeping default behavior the same This allows gradient boosters to turn off presorting when building deep trees or using sparse data By Jacob Schreiber
 - Alteredmetricsroccurve to drop unnecessary thresholds by default By Graham Clenaghan
 - AddedfeatureselectionSelectFromModel metatransformer which can be used along with estimators that have coef orfeatureimportances attribute to select important features of the input data By Maheshakya Wijewardena Joel Nothman and Manoj Kumar
 - Addedmetricspairwiselaplaciankernel By Clyde Fare
 - covarianceGraphLasso allows separate control of the convergence criterion for the ElasticNet subproblem via the enettol parameter
 - Improved verbosity in decompositionDictionaryLearning
 - ensembleRandomForestClassifier andensembleRandomForestRegressor no longer explicitly store the samples used in bagging resulting in a much reduced memory footprint for storing random forest models
 - Addedpositive option tolinearmodelLars andlinearmodelLarsPath to force coefficients to be positive 5131
 - Added the Xnormsquared parameter to metricspairwiseeuclideananddistances to provide precomputed squared norms for X
 - Added the fitpredict method topipelinePipeline
- 90 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Added the preprocessingminmaxscale function

Bug fixes

- Fixed nondeterminism in dummyDummyClassifier with sparse multilabel output By Andreas Müller
- Fixed the output shape of linearmodelRANSACRegressor tonsamples By Andreas Müller
- Fixed bug in decompositionDictLearning when njobs = 0 By Andreas Müller
- Fixed bug where gridsearchRandomizedSearchCV could consume a lot of memory for large discrete grids By Joel Nothman
- Fixed bug in linearmodelLogisticRegressionCV where penalty was ignored in the final fit By Manoj Kumar
- Fixed bug in ensembleforestForestClassifier while computing oobscore and X is a sparse matrix By Ankur Ankan
- All regressors now consistently handle and warn when given y that is of shape n samples 1 By Andreas Müller and Henry Lin 5431
- Fix in clusterKMeans cluster reassignment for sparse input by Lars Buitinck
- Fixed a bug in lassoLDA that could cause asymmetric covariance matrices when using shrinkage By Martin Billinger
- Fixed crossvalidationcrossvalpredict for estimators with sparse predictions By Buddha Prakash
- Fixed the predict_proba method of linearmodelLogisticRegression to use softmax instead of onevsrest normalization By Manoj Kumar 5182
- Fixed the partial_fit method of linearmodelSGDClassifier when called with average=True By Andrew Lamb 5282
- Dataset fetchers use different filenames under Python 2 and Python 3 to avoid pickling compatibility issues By Olivier Grisel 5355
- Fixed a bug in naivebayesGaussianNB which caused classification results to depend on scale By Jake Vanderplas
- Fixed temporarily linearmodelRidge which was incorrect when fitting the intercept in the case of sparse data The fix automatically changes the solver to 'sag' in this case 5360 by Tom Dupre la Tour
- Fixed a performance bug in decompositionRandomizedPCA on data with a large number of features and fewer samples 4478 By Andreas Müller Loic Esteve and Giorgio Patrini
- Fixed bug in crossdecompositionPLS that yielded unstable and platform dependent output and failed on fit_transform By Arthur Mensch
- Fixes to the Bunch class used to store datasets
- Fixed ensembleplotpartialdependence ignoring the percentiles parameter
- Providing a set as vocabulary in CountVectorizer no longer leads to inconsistent results when pickling
- Fixed the conditions on when a precomputed Gram matrix needs to be recomputed in linearmodelLinearRegression linearmodelOrthogonalMatchingPursuit linearmodelLasso and linearmodelElasticNet
- Fixed inconsistent memory layout in the coordinate descent solver that affected linearmodelDictionaryLearning and covarianceGraphLasso 5337 By Olivier Grisel

117 Previous Releases 91

scikitlearn user guide Release 0213

- manifoldLocallyLinearEmbedding no longer ignores the reg parameter
- Nearest Neighbor estimators with custom distance metrics can now be pickled 4362
- Fixed a bug in pipelineFeatureUnion wheretransformerweights were not properly handled when performing gridsearches
- Fixed a bug in linearmodelLogisticRegression andlinearmodelLogisticRegressionCV when using classweightbalanced orclassweightauto

By Tom Dupre la Tour

- Fixed bug 5495 when doing OVRSVCDdecisionfunctionsshape"ovr" Fixed by Elvis Dohmatob
- API (Application Programming Interface) changes summary
- Attribute datamin datamax anddatarange inpreprocessingMinMaxScaler are deprecated and won't be available from 019 Instead the class now exposes datamin datamax and datarange By Giorgio Patrini
 - All Scaler classes now have an scale attribute the featurewise rescaling applied by their transform methods The old attribute std inpreprocessingStandardScaler is deprecated and superseded by scale it won't be available in 019 By Giorgio Patrini
 - svmSVC andsvmNuSVC now have an decisionfunctionsshape parameter to make their decision function of shape nsamples nclasses by settingdecisionfunctionsshapeovr This will be the default behavior starting in 019 By Andreas Müller
 - Passing 1D data arrays as input to estimators is now deprecated as it caused confusion in how the array elements should be interpreted as features or as samples All data arrays are now expected to be explicitly shaped nsamples nfeatures By Vighnesh Birodkar
 - ldaLDA andqdaQDA have been moved to discriminantanalysis LinearDiscriminantAnalysis and discriminantanalysis QuadraticDiscriminantAnalysis
 - Thestorecovariance andtol parameters have been moved from the fit method to the constructor in discriminantanalysisLinearDiscriminantAnalysis and thestorecovariances and tol parameters have been moved from the fit method to the constructor in discriminantanalysis QuadraticDiscriminantAnalysis
 - Models inheriting from LearntSelectorMixin will no longer support the transform methods ie RandomForests GradientBoosting LogisticRegression DecisionTrees SVMs and SGD related models Wrap these models around the metatransformer featureselectionSelectFromModel to remove features according to coefs orfeatureimportances which are below a certain threshold value instead
 - clusterKMeans reruns clusterassignments in case of nonconvergence to ensure consistency of predictX andlabels By Vighnesh Birodkar
 - Classifier and Regressor models are now tagged as such using the estimatortype attribute
 - Crossvalidation iterators always provide indices into training and test set not boolean masks
 - Thedecisionfunction on all regressors was deprecated and will be removed in 019 Use predict instead
 - datasetsloadlfwpairs is deprecated and will be removed in 019 Use datasets fetchlfwpairs instead
 - The deprecated hmm module was removed
 - The deprecated Bootstrap crossvalidation iterator was removed

scikitlearn user guide Release 0213

- The deprecated Ward andWardAgglomerative classes have been removed Use clustering AgglomerativeClustering instead
- crossvalidationcheckcv is now a public function
- The property residues oflinearmodelLinearRegression is deprecated and will be removed in 019
- The deprecated njobs parameter of linearmodelLinearRegression has been moved to the constructor
- Removed deprecated classweight parameter from linearmodelSGDClassifier 'sfit method Use the construction parameter instead
- The deprecated support for the sequence of sequences or list of lists multilabel format was removed To convert to and from the supported binary indicator matrix format use MultiLabelBinarizer
- The behavior of calling the inversetransform method ofPipelinepipeline will change in 019 It will no longer reshape onedimensional input to twodimensional input
- The deprecated attributes indicatormatrix multilabel andclasses ofpreprocessing LabelBinarizer were removed
- Usinggamma0 insvmSVC andsvmSVR to automatically set the gamma to 1 nfeatures is deprecated and will be removed in 019 Use gammaauto instead

1179 Version 0161

April 14 2015

117 Previous Releases 93

scikitlearn user guide Release 0213

Changelog

Bug fixes

- Allow input data larger than blocksize in `covarianceLedoitWolf` by Andreas Müller
- Fix a bug in `isotonicIsotonicRegression` deduplication that caused unstable result in `calibrationCalibratedClassifierCV` by Jan Hendrik Metzen
- Fix sorting of labels in `func preprocessingLabelBinarize` by Michael Heilman
- Fix several stability and convergence issues in `crossdecompositionCCA` and `crossdecompositionPLSCanonical` by Andreas Müller
- Fix a bug in `clusterKMeans` when `precomputedDistances=False` on fortran ordered data
- Fix a speed regression in `ensembleRandomForestClassifier` 's `predict` and `predict_proba` by Andreas Müller
- Fix a regression where `utilsshuffle` converted lists and dataframes to arrays by Olivier Grisel

11710 Version 016

March 26 2015

Highlights

- Speed improvements notably in `clusterDBSCAN` reduced memory requirements bugfixes and better default settings
- Multinomial Logistic regression and a path algorithm in `linearModelLogisticRegressionCV`
- Out of core learning of PCA (Principal Component Analysis) via `decompositionIncrementalPCA`
- Probability calibration of classifiers using `calibrationCalibratedClassifierCV`
- `clusterBirch` clustering method for large scale datasets
- Scalable approximate nearest neighbors search with Locality sensitive hashing forests in `neighborsLSHForest`
- Improved error messages and better validation when using malformed input data
- More robust integration with pandas dataframes

Changelog

New features

- The new `neighborsLSHForest` implements locality sensitive hashing for approximate nearest neighbors search By Maheshakya Wijewardena
- Added `svmLinearSVR` This class uses the liblinear implementation of Support Vector Regression which is much faster for large sample sizes than `svmSVR` with linear kernel By Fabian Pedregosa and Qiang Luo
- Incremental fit for `GaussianNB`
- Added `sample_weight` support to `dummyDummyClassifier` and `dummyDummyRegressor` By Arnaud Joly

scikitlearn user guide Release 0213

- Added the metricslabelrankingaverageprecisionscore metrics By Arnaud Joly
 - Add themetricscoverageerror metrics By Arnaud Joly
 - AddedlinearmodelLogisticRegressionCV By Manoj Kumar Fabian Pedregosa Gael Varoquaux and Alexandre Gramfort
 - Addedwarmstart constructor parameter to make it possible for any trained forest model to grow additional trees incrementally By Laurent Direr
 - Addedsampleweight support to ensembleGradientBoostingClassifier andensemble GradientBoostingRegressor By Peter Prettenhofer
 - AddeddecompositionIncrementalPCA an implementation of the PCA (Principal Component Analysis) algorithm that supports out ofcore learning with a partialfit method By Kyle Kastner
 - Averaged SGD for SGDClassifier andSGDRegressor By Danny Sullivan
 - Addedcrossvalpredict function which computes crossvalidated estimates By Luis Pedro Coelho
 - AddedlinearmodelTheilSenRegressor a robust generalizedmedianbased estimator By Florian Wilhelm
 - Addedmetricsmedianabsoluteerror a robust metric By Gael Varoquaux and Florian Wilhelm
 - AddedclusterBirch an online clustering algorithm By Manoj Kumar Alexandre Gramfort and Joel Nothman
 - Added shrinkage support to discriminantanalysisLinearDiscriminantAnalysis using two new solvers By Clemens Brunner and Martin Billinger
 - AddedkernelridgeKernelRidge an implementation of kernelized ridge regression By Mathieu Blondel and Jan Hendrik Metzen
 - All solvers in linearmodelRidge now support sampleweight By Mathieu Blondel
 - AddedcrossvalidationPredefinedSplit crossvalidation for fixed userprovided crossvalidation folds By Thomas Unterthiner
 - AddedcalibrationCalibratedClassifierCV an approach for calibrating the predicted probabilities of a classifier By Alexandre Gramfort Jan Hendrik Metzen Mathieu Blondel and Balazs Kegl
- Enhancements
- Add option returndistance inhierarchicalwardtree to return distances between nodes for both structured and unstructured versions of the algorithm By Matteo Visconti di Oleggio Castello The same option was added in hierarchicallinkagetree By Manoj Kumar
 - Add support for sample weights in scorer objects Metrics with sample weight support will automatically benefit from it By Noel Dawe and Vlad Niculae
 - Addednewtoncg andlbfgs solver support in linearmodelLogisticRegression By Manoj Kumar
 - Addselectionrandom parameter to implement stochastic coordinate descent for linearmodel Lasso linearmodelElasticNet and related By Manoj Kumar
 - Addsampleweight parameter to metricsjaccardsimilarityscore andmetrics logloss By Jatin Shah
 - Support sparse multilabel indicator representation in preprocessingLabelBinarizer and multiclassOneVsRestClassifier by Hamzeh Alsalhi with thanks to Rohit Sivaprasad as well as evaluation metrics by Joel Nothman
- 117 Previous Releases 95

scikitlearn user guide Release 0213

- Addsampleweight parameter to metricsjaccardsimilarityscore ByJatin Shah
 - Add support for multiclass in metricshingeloss AddedlabelsNone as optional parameter By Saurabh Jha
 - Addsampleweight parameter to metricshingeloss BySaurabh Jha
 - Addmulticlassmultinomial option inlinearmodelLogisticRegression to implement a Logistic Regression solver that minimizes the crossentropy or multinomial loss instead of the default OnevsRest setting Supports lbfgs andnewtoncg solvers By Lars Buitinck and Manoj Kumar Solver optionnewtoncg by Simon Wu
 - DictVectorizer can now perform fittransform on an iterable in a single pass when giving the option sortFalse By Dan Blanchard
 - GridSearchCV andRandomizedSearchCV can now be configured to work with estimators that may fail and raise errors on individual folds This option is controlled by the errorscore parameter This does not affect errors raised on refit By Michal Romaniuk
 - Adddigits parameter to metricsclassificationreport to allow report to show different precision of floating point numbers By Ian Gilmore
 - Add a quantile prediction strategy to the dummyDummyRegressor By Aaron Staple
 - Addhandleunknown option to preprocessingOneHotEncoder to handle unknown categorical features more gracefully during transform By Manoj Kumar
 - Added support for sparse input data to decision trees and their ensembles By Fares Hedyati and Arnaud Joly
 - Optimized clusterAffinityPropagation by reducing the number of memory allocations of large temporary datastructures By Antony Lee
 - Parallelization of the computation of feature importances in random forest By Olivier Grisel and Arnaud Joly
 - Addniter attribute to estimators that accept a maxiter attribute in their constructor By Manoj Kumar
 - Added decision function for multiclassOneVsOneClassifier By Raghav RV and Kyle Beauchamp
 - neighborskneighborsgraph andradiusneighborsgraph support nonEuclidean metrics By Manoj Kumar
 - Parameter connectivity inclusterAgglomerativeClustering and family now accept callables that return a connectivity matrix By Manoj Kumar
 - Sparse support for paireddistances By Joel Nothman
 - clusterDBSCAN now supports sparse input and sample weights and has been optimized the inner loop has been rewritten in Cython and radius neighbors queries are now computed in batch By Joel Nothman and Lars Buitinck
 - Addclassweight parameter to automatically weight samples by class frequency for ensembleRandomForestClassifier treeDecisionTreeClassifier ensemble ExtraTreesClassifier andtreeExtraTreeClassifier By Trevor Stephens
 - gridsearchRandomizedSearchCV now does sampling without replacement if all parameters are given as lists By Andreas Müller
 - Parallelized calculation of pairwisedistances is now supported for scipy metrics and custom callables By Joel Nothman
 - Allow the fitting and scoring of all clustering algorithms in pipelinePipeline By Andreas Müller
 - More robust seeding and improved error messages in clusterMeanShift by Andreas Müller
- 96 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Make the stopping criterion for mixtureGMM mixtureDPGMM andmixtureVBGMM less dependent on the number of samples by thresholding the average loglikelihood change instead of its sum over all samples By Hervé Bredin

- The outcome of manifoldspectralembedding was made deterministic by flipping the sign of eigen vectors By Hasil Sharma

- Significant performance and memory usage improvements in preprocessingPolynomialFeatures By Eric Martin

- Numerical stability improvements for preprocessingStandardScaler andpreprocessing scale By Nicolas Goix

- svmSVC fitted on sparse input now implements decisionfunction By Rob Zinkov and Andreas Müller

- crossvalidationtraintestsplit now preserves the input type instead of converting to numpy arrays

Documentation improvements

- Added example of using FeatureUnion for heterogeneous input By Matt Terry

- Documentation on scorers was improved to highlight the handling of loss functions By Matt Pico

- A discrepancy between liblinear output and scikitlearn’s wrappers is now noted By Manoj Kumar

- Improved documentation generation examples referring to a class or function are now shown in a gallery on the classfunction’s API (Application Programming Interface) reference page By Joel Nothman

- More explicit documentation of sample generators and of data transformation By Joel Nothman

- sklearnneighborsBallTree andsklearnneighborsKDTree used to point to empty pages

stating that they are aliases of BinaryTree This has been fixed to show the correct class docs By Manoj Kumar

- Added silhouette plots for analysis of KMeans clustering using metricssilhouettesamples and metricssilhouettescore See Selecting the number of clusters with silhouette analysis on KMeans clustering

Bug fixes

- Metaestimators now support ducktyping for the presence of decisionfunction

predictproba and other methods This fixes behavior of gridsearchGridSearchCV

gridsearchRandomizedSearchCV pipelinePipeline featuresselectionRFE

featuresselectionRFECV when nested By Joel Nothman

- Thescoring attribute of gridsearch and crossvalidation methods is no longer ignored when a

gridsearchGridSearchCV is given as a base estimator or the base estimator doesn’t have predict

- The function hierarchicalwardtree now returns the children in the same order for both the structured and unstructured versions By Matteo Visconti di Oleggio Castello

- featuresselectionRFECV now correctly handles cases when step is not equal to 1 By Nikolay Mayorov

- ThedecompositionPCA now undoes whitening in its inversetransform Also itscomponents now always have unit length By Michael Eickenberg

- Fix incomplete download of the dataset when datasetsdownload20newsgroups is called By Manoj Kumar

117 Previous Releases 97

scikitlearn user guide Release 0213

- Various fixes to the Gaussian processes subpackage by Vincent Dubourg and Jan Hendrik Metzen
- Callingpartialfit withclassweightauto throws an appropriate error message and suggests a work around By Danny Sullivan
- RBFSampler withgammag formerly approximated rbfkernel withgammag2 the definition of gamma is now consistent which may substantially change your results if you use a fixed value If you cross validated over gamma it probably doesn't matter too much By Dougal Sutherland
- Pipeline object delegate the classes attribute to the underlying estimator It allows for instance to make bagging of a pipeline object By Arnaud Joly
- neighborsNearestCentroid now uses the median as the centroid when metric is set to manhattan It was using the mean before By Manoj Kumar
- Fix numerical stability issues in linearmodelSGDClassifier andlinearmodelSGDRegressor by clipping large gradients and ensuring that weight decay rescaling is always positive for large l2 regularization and large learning rate values By Olivier Grisel
- Whencomputealltree is set to "auto" the full tree is built when nclusters is high and is early stopped when nclusters is low while the behavior should be viceversa in clusterAgglomerativeClustering and friends This has been fixed By Manoj Kumar
- Fix lazy centering of data in linearmodelenetpath andlinearmodellassopath It was centered around one It has been changed to be centered around the origin By Manoj Kumar
- Fix handling of precomputed affinity matrices in clusterAgglomerativeClustering when using connectivity constraints By Cathy Deng
- Correctpartialfit handling of classprior forsklearnnaivebayesMultinomialNB andsklearnnaivebayesBernoulliNB By Trevor Stephens
- Fixed a crash in metricsprecisionrecallfscoresupport when using unsorted labels in the multilabel setting By Andreas Müller
- Avoid skipping the first nearest neighbor in the methods radiusneighbors kneighbors kneighborsgraph andradiusneighborsgraph insklearnneighborsNearestNeighbors and family when the query data is not the same as fit data By Manoj Kumar
- Fix logdensity calculation in the mixtureGMM with tied covariance By Will Dawson
- Fixed a scaling error in featureselectionSelectFdr where a factor nfeatures was missing By Andrew Tulloch
- Fix zero division in neighborsKNeighborsRegressor and related classes when using distance weighting and having identical data points By GarretR
- Fixed round off errors with non positivedefinite covariance matrices in GMM By Alexis Mignon
- Fixed a error in the computation of conditional probabilities in naivebayesBernoulliNB By Hanna Wallach
- Make the method radiusneighbors ofneighborsNearestNeighbors return the samples lying on the boundary for algorithmbrute By Yan Yi
- Flip sign of dualcoef ofsvmSVC to make it consistent with the documentation and decisionfunction By Artem Sobolev
- Fixed handling of ties in isotonicIsotonicRegression We now use the weighted average of targets secondary method By Andreas Müller and Michael Bommarito

scikitlearn user guide Release 0213

API (Application Programming Interface) changes summary

- GridSearchCV andcrossvalscore and other metaestimators don't convert pandas DataFrames into arrays any more allowing DataFrame specific operations in custom estimators
- multiclassfitovr multiclasspredictovr predictprobaovr multiclassfitovo multiclasspredictovo multiclassfitecoc andmulticlasspredictecoc are deprecated Use the underlying estimators instead
- Nearest neighbors estimators used to take arbitrary keyword arguments and pass these to their distance metric

This will no longer be supported in scikitlearn 018 use the metricparams argument instead

- njobs parameter of the fit method shifted to the constructor of the LinearRegression class
- Thepredictproba method ofmulticlassOneVsRestClassifier now returns two probabilities per sample in the multiclass case this is consistent with other estimators and with the method's documentation but previous versions accidentally returned only the positive probability Fixed by Will Lamond and Lars Buitinck

- Change default value of precompute in ElasticNet andLasso to False Setting precompute to "auto" was found to be slower when nsamples nfeatures since the computation of the Gram matrix is computationally expensive and outweighs the benefit of fitting the Gram for just one alpha precomputeauto is now deprecated and will be removed in 018 By Manoj Kumar

- Exposepositive option inlinearmodelenetpath andlinearmodelenetpath which constrains coefficients to be positive By Manoj Kumar
- Users should now supply an explicit average parameter to sklearnmetricsf1score sklearnmetricsfbetascore sklearnmetricsrecallscore andsklearnmetricsprecisionscore when performing multiclass or multilabel ie not binary classification By Joel Nothman

- scoring parameter for cross validation now accepts f1micro f1macro orf1weighted f1 is now for binary classification only Similar changes apply to precision andrecall By Joel Nothman

- Thefitintercept normalize andreturnmodels parameters in linearmodelenetpath andlinearmodellassopath have been removed They were deprecated since 014

- From now onwards all estimators will uniformly raise NotFittedError utilsvalidation NotFittedError when any of the predict like methods are called before the model is fit By Raghav RV

- Input data validation was refactored for more consistent input validation The checkarrays function was replaced by checkarray andcheckXy By Andreas Müller

- AllowXNone in the methods radiusneighbors kneighbors kneighborsgraph and radiusneighborsgraph insklearnneighborsNearestNeighbors and family If set to None then for every sample this avoids setting the sample itself as the first nearest neighbor By Manoj Kumar

- Add parameter includeself inneighborskneighborsgraph andneighborsradiusneighborsgraph which has to be explicitly set by the user If set to True then the sample itself is considered as the first nearest neighbor

- thresh parameter is deprecated in favor of new tol parameter in GMDPGMM andVBGMM See Enhancements section for details By Hervé Bredin

- Estimators will treat input with dtype object as numeric when possible By Andreas Müller
- Estimators now raise ValueError consistently when fitted on empty data less than 1 sample or less than 1 feature for 2D input By Olivier Grisel

scikitlearn user guide Release 0213

- Theshuffle option of linearmodelSGDClassifier linearmodelSGDRegressor linearmodelPerceptron linearmodelPassiveAggressiveClassifier and linearmodelPassiveAggressiveRegressor now defaults to True
- clusterDBSCAN now uses a deterministic initialization The randomstate parameter is deprecated By Erich Schubert

11711 Version 0152

September 4 2014

Bug fixes

- Fixed handling of the pparameter of the Minkowski distance that was previously ignored in nearest neighbors models By Nikolay Mayorov
- Fixed duplicated alphas in linearmodelLassoLars with early stopping on 32 bit Python By Olivier Grisel and Fabian Pedregosa
- Fixed the build under Windows when scikitlearn is built with MSVC while NumPy is built with MinGW By Olivier Grisel and Federico Vaggi
- Fixed an array index overflow bug in the coordinate descent solver By Gael Varoquaux
- Better handling of numpy 19 deprecation warnings By Gael Varoquaux
- Removed unnecessary data copy in clusterKMeans By Gael Varoquaux
- Explicitly close open files to avoid ResourceWarnings under Python 3 By Calvin Giles

100 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Thetransform ofdiscriminantanalysisLinearDiscriminantAnalysis now projects the input on the most discriminant directions By Martin Billinger
- Fixed potential overflow in treesaferealloc by Lars Buitinck
- Performance optimization in isotonicIsotonicRegression By Robert Bradshaw
- nose is nonlonger a runtime dependency to import sklearn only for running the tests By Joel Nothman
- Many documentation and website fixes by Joel Nothman Lars Buitinck Matt Pico and others

11712 Version 0151

August 1 2014

Bug fixes

- Madecrossvalidationcrossvalscore usecrossvalidationKFold instead of crossvalidationStratifiedKFold on multioutput classification problems By Nikolay Mayorov
- Support unseen labels preprocessingLabelBinarizer to restore the default behavior of 0141 for backward compatibility By Hamzeh Alsalhi
- Fixed the clusterKMeans stopping criterion that prevented early convergence detection By Edward Raff and Gael Varoquaux
- Fixed the behavior of multiclassOneVsOneClassifier in case of ties at the perclass vote level by computing the correct perclass sum of prediction scores By Andreas Müller
- Madecrossvalidationcrossvalscore andgridsearchGridSearchCV accept Python lists as input data This is especially useful for crossvalidation and model selection of text processing pipelines By Andreas Müller
- Fixed data input checks of most estimators to accept input data that implements the NumPy array protocol This is the case for for pandasSeries andpandasDataFrame in recent versions of pandas By Gael Varoquaux
- Fixed a regression for linearmodelSGDClassifier withclassweightauto on data with noncontiguous labels By Olivier Grisel

11713 Version 015

July 15 2014

Highlights

- Many speed and memory improvements all across the code
- Huge speed and memory improvements to random forests and extra trees that also benefit better from parallel computing
- Incremental fit to BernoulliRBM
- AddedclusterAgglomerativeClustering for hierarchical agglomerative clustering with average linkage complete linkage and ward strategies
- AddedlinearmodelRANSACRegressor for robust regression models

117 Previous Releases 101

scikitlearn user guide Release 0213

- Added dimensionality reduction with manifoldTSNE which can be used to visualize highdimensional data

Changelog

New features

- AddedensembleBaggingClassifier andensembleBaggingRegressor metaestimators for ensembling any kind of base estimator See the Bagging section of the user guide for details and examples

By Gilles Louppe

- New unsupervised feature selection algorithm featuresselectionVarianceThreshold by Lars

Buitinck

- AddedlinearmodelRANSACRegressor metaestimator for the robust fitting of regression models By

Johannes Schönberger

- AddedclusterAgglomerativeClustering for hierarchical agglomerative clustering with average linkage complete linkage and ward strategies by Nelle Varoquaux and Gael Varoquaux
- Shorthand constructors pipelinemakepipeline andpipelinemakeunion were added by Lars

Buitinck

- Shuffle option for crossvalidationStratifiedKfold By Jeffrey Blackburne
- Incremental learning partialfit for Gaussian Naive Bayes by Imran Haque
- Addedpartialfit toBernoulliRBM By Danny Sullivan
- Addedlearningcurve utility to chart performance with respect to training size See Plotting Learning

Curves By Alexander Fabisch

- Add positive option in LassoCV andElasticNetCV By Brian Wignall and Alexandre Gramfort
- AddedlinearmodelMultiTaskElasticNetCV andlinearmodelMultiTaskLassoCV By

Manoj Kumar

- AddedmanifoldTSNE By Alexander Fabisch

Enhancements

- Add sparse input support to ensembleAdaBoostClassifier andensemble

AdaBoostRegressor metaestimators By Hamzeh Alsalhi

- Memory improvements of decision trees by Arnaud Joly
- Decision trees can now be built in bestfirst manner by using maxleafnodes as the stopping criteria

Refactored the tree code to use either a stack or a priority queue for tree building By Peter Prettenhofer and

Gilles Louppe

- Decision trees can now be fitted on fortran and cstyle arrays and noncontinuous arrays without the need to make a copy If the input array has a different dtype than npfloat32 a fortran style copy will be made since fortranstyle memory layout has speed advantages By Peter Prettenhofer and Gilles Louppe
- Speed improvement of regression trees by optimizing the the computation of the mean square error criterion

This lead to speed improvement of the tree forest and gradient boosting tree modules By Arnaud Joly

- Theimgtograph andgridtograph functions in sklearnfeatureextractionimage now returnnpndarray instead ofnpmatrix whenreturnasnpndarray See the Notes section for more information on compatibility

102 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Changed the internal storage of decision trees to use a struct array This fixed some small bugs while improving code and providing a small speed gain By Joel Nothman
 - Reduce memory usage and overhead when fitting and predicting with forests of randomized trees in parallel with `n_jobs = 1` by leveraging new threading backend of `joblib 0.8` and releasing the GIL in the tree fitting Cython code By Olivier Grisel and Gilles Louppe
 - Speed improvement of the `sklearn.ensemble.gradientboosting` module By Gilles Louppe and Peter Prettenhofer
 - Various enhancements to the `sklearn.ensemble.gradientboosting` module
 - `allow_warm_start` argument to fit additional trees
 - `max_leaf_nodes` argument to fit GBM style trees
 - `monitor` fit argument to inspect the estimator during training and refactoring of the verbose code By Peter Prettenhofer
 - `FastSklearnEnsembleExtraTrees` by caching feature values By Arnaud Joly
 - Faster depthbased tree building algorithm such as decision tree random forest extra trees or gradient tree boosting with depth based growing strategy by avoiding trying to split on found constant features in the sample subset By Arnaud Joly
 - `AdaptiveMinWeightFractionLeaf` prepruning parameter to treebased methods the minimum weighted fraction of the input samples required to be at a leaf node By Noel Dawe
 - Added `metrics.pairwise_distances_argmin_min` by Philippe Gervais
 - Added `predict` method to `cluster.AffinityPropagation` and `cluster.MeanShift` by Mathieu Blondel
 - Vector and matrix multiplications have been optimised throughout the library by Denis Engemann and Alexandre Gramfort In particular they should take less memory with older NumPy versions prior to 1.7.2
 - `PrecisionRecall` and `ROC` examples now use `train_test_split` and have more explanation of why these metrics are useful By Kyle Kastner
 - The training algorithm for `decomposition.NMF` is faster for sparse matrices and has much lower memory complexity meaning it will scale up gracefully to large datasets By Lars Buitinck
 - Added `svd_method` option with default value to “randomized” to `decomposition.FactorAnalysis` to save memory and significantly speedup computation by Denis Engemann and Alexandre Gramfort
 - Changed `cross_validation.StratifiedKFold` to try and preserve as much of the original ordering of samples as possible so as not to hide overfitting on datasets with a nonnegligible level of samples dependency By Daniel Nouri and Olivier Grisel
 - Add multioutput support to `gaussian_process.GaussianProcess` by John Novak
 - Support for precomputed distance matrices in nearest neighbor estimators by Robert Layton and Joel Nothman
 - Norm computations optimized for NumPy 1.6 and later versions by Lars Buitinck In particular the `kmeans` algorithm no longer needs a temporary data structure the size of its input
 - `DummyClassifier` can now be used to predict a constant output value By Manoj Kumar
 - `DummyRegressor` has now a `strategy` parameter which allows to predict the mean the median of the training set or a constant output value By Maheshakya Wijewardena
 - Multilabel classification output in multilabel indicator format is now supported by `metrics` `roc_auc_score` and `metrics.average_precision_score` by Arnaud Joly
 - Significant performance improvements more than 100x speedup for large problems in `isotonic` `IsotonicRegression` by Andrew Tulloch
 - Speed and memory usage improvements to the `SGD` algorithm for linear models it now uses threads not separate processes when `n_jobs=1` By Lars Buitinck
- 117 Previous Releases 103

scikitlearn user guide Release 0213

- Grid search and cross validation allow NaNs in the input arrays so that preprocessors such as preprocessingImputer can be trained within the cross validation loop avoiding potentially skewed results
- Ridge regression can now deal with sample weights in feature space only sample space until then By Michael Eickenberg Both solutions are provided by the Cholesky solver
- Several classification and regression metrics now support weighted samples with the new sampleweight argument metricsaccuracy score metricszeroone loss metricsprecision score metricsaverage precision score metrics f1 score metricsfbeta score metricsrecall score metricsrocauc score metricsexplained variance score metricsmeansquared error metrics mean absolute error metricsr2 score By Noel Dawe
- Speed up of the sample generator datasetsmake multilabel classification By Joel Nothman
- Documentation improvements
- The Working With Text Data tutorial has now been worked in to the main documentation's tutorial section Includes exercises and skeletons for tutorial presentation Original tutorial created by several authors including Olivier Grisel Lars Buitinck and many others Tutorial integration into the scikitlearn documentation by Jaques Grobler
- Added Computational Performance documentation Discussion and examples of prediction latency throughput and different factors that have influence over speed Additional tips for building faster models and choosing a relevant compromise between speed and predictive power By Eustache Diemert
- Bug fixes
- Fixed bug in decomposition MiniBatchDictionaryLearning partial fit was not working properly
- Fixed bug in linear model stochastic gradient l1 ratio was used as 10 l1 ratio
- Fixed bug in multiclass OneVsOne Classifier with string labels
- Fixed a bug in LassoCV and ElasticNetCV they would not precompute the Gram matrix with precompute True or precompute auto and n samples n features By Manoj Kumar
- Fixed incorrect estimation of the degrees of freedom in feature selection regression when variables are not centered By Virgile Fritsch
- Fixed a race condition in parallel processing with dispatch all for instance in cross_val_score By Olivier Grisel
- Raise error in cluster Feature Agglomeration and cluster Ward Agglomeration when no samples are given rather than returning meaningless clustering
- Fixed bug in gradient boosting Gradient Boosting Regressor with loss huber gamma might have not been initialized
- Fixed feature importances as computed with a forest of randomized trees when fit with sample weight None and/or with bootstrap True By Gilles Louppe

scikitlearn user guide Release 0213

API (Application Programming Interface) changes summary

- sklearnhmm is deprecated Its removal is planned for the 017 release
- Use of covarianceEllipticEnvelop has now been removed after deprecation Please use covarianceEllipticEnvelope instead
- clusterWard is deprecated Use clusterAgglomerativeClustering instead
- clusterWardClustering is deprecated Use
- clusterAgglomerativeClustering instead
- crossvalidationBootstrap is deprecated crossvalidationKFold or crossvalidationShuffleSplit are recommended instead
- Direct support for the sequence of sequences or list of lists multilabel format is deprecated To convert to and from the supported binary indicator matrix format use MultiLabelBinarizer By Joel Nothman
- Add score method to PCA (Principal Component Analysis) following the model of probabilistic PCA (Principal Component Analysis) and deprecate model whose score implementation is not correct The computation now also exploits the matrix inversion lemma for faster computation By Alexandre Gramfort
- The score method of FactorAnalysis now returns the average loglikelihood of the samples Use scoresamples to get loglikelihood of each sample By Alexandre Gramfort
- Generating boolean masks the setting indicesFalse from crossvalidation generators is deprecated Support for masks will be removed in 017 The generators have produced arrays of indices by default since 010 By Joel Nothman
- 1d arrays containing strings with dtypeobject as used in Pandas are now considered valid classification targets This fixes a regression from version 013 in some classifiers By Joel Nothman
- Fix wrong explainedvarianceratio attribute in RandomizedPCA By Alexandre Gramfort
- Fit alphas for each l1ratio instead of meanl1ratio inlinearmodelElasticNetCV and linearmodelLassoCV This changes the shape of alphas fromnalphas tonl1ratio nalphas if thel1ratio provided is a 1D array like object of length greater than one By Manoj Kumar
- FixlinearmodelElasticNetCV andlinearmodelLassoCV when fitting intercept and input data is sparse The automatic grid of alphas was not computed correctly and the scaling with normalize was wrong By Manoj Kumar
- Fix wrong maximal number of features drawn maxfeatures at each split for decision trees random forests and gradient tree boosting Previously the count for the number of drawn features started only after one non constant features in the split This bug fix will affect computational and generalization performance of those algorithms in the presence of constant features To get back previous generalization performance you should modify the value of maxfeatures By Arnaud Joly
- Fix wrong maximal number of features drawn maxfeatures at each split for ensemble ExtraTreesClassifier andensembleExtraTreesRegressor Previously only non constant features in the split was counted as drawn Now constant features are counted as drawn Furthermore at least one feature must be non constant in order to make a valid split This bug fix will affect computational and generalization performance of extra trees in the presence of constant features To get back previous generalization performance you should modify the value of maxfeatures By Arnaud Joly
- Fixutilscomputeclasseweight whenclasseweightauto Previously it was broken for input of noninteger dtype and the weighted array that was returned was wrong By Manoj Kumar
- FixcrossvalidationBootstrap to returnValueError whennttrain ntest n By Ronald Phlypo

11714 Version 014

August 7 2013

Changelog

- Missing values with sparse and dense matrices can be imputed with the transformer preprocessing Imputer by Nicolas Trésegnie
- The core implementation of decisions trees has been rewritten from scratch allowing for faster tree induction and lower memory consumption in all treebased estimators By Gilles Louppe
- AddedensembleAdaBoostClassifier andensembleAdaBoostRegressor by Noel Dawe and Gilles Louppe See the AdaBoost section of the user guide for details and examples
- AddedgridsearchRandomizedSearchCV andgridsearchParameterSampler for randomized hyperparameter optimization By Andreas Müller
- Added biclustering algorithms sklearnclusterbiclusterSpectralCoclustering and sklearnclusterbiclusterSpectralBiclustering data generation methods sklearn datasetsmakebiclusters andsklearndatasetsmakecheckerboard and scoring metrics sklearnmetricsconsensussscore By Kemal Eren
- Added Restricted Boltzmann Machines neuralnetworkBernoulliRBM By Yann Dauphin

110 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Python 3 support by Justin Vincent Lars Buitinck Subhdeep Moitra and Olivier Grisel All tests now pass under Python 33
 - Ability to pass one penalty alpha value per target in linearmodelRidge by eickenberg and Mathieu Blondel
 - Fixedsklearnlinearmodelstochasticgradientpy L2 regularization issue minor practical significance By Norbert Crombach and Mathieu Blondel
 - Added an interactive version of Andreas Müller’s Machine Learning Cheat Sheet for scikitlearn to the documentation See Choosing the right estimator By Jaques Grobler
 - gridsearchGridSearchCV andcrossvalidationcrossvalscore now support the use of advanced scoring function such as area under the ROC curve and fbeta scores See The scoring parameter defining model evaluation rules for details By Andreas Müller and Lars Buitinck Passing a function from sklearnmetrics asscorefunc is deprecated
 - Multilabel classification output is now supported by metricsaccuracy score metricszeroone loss metricsf1 score metricsfbeta score metrics classificationreport metricsprecision score andmetricsrecall score by Arnaud Joly
 - Two new metrics metricshammingloss andmetricsjaccardsimilarity score are added with multilabel support by Arnaud Joly
 - Speed and memory usage improvements in featureextractiontextCountVectorizer and featureextractiontextTfidfVectorizer by Jochen Wersdörfer and Roman Sinayev
 - Themindf parameter in featureextractiontextCountVectorizer and featureextractiontextTfidfVectorizer which used to be 2 has been reset to 1 to avoid unpleasant surprises empty vocabularies for novice users who try it out on tiny document collections A value of at least 2 is still recommended for practical use
 - svmLinearSVC linearmodelSGDClassifier andlinearmodelSGDRegressor now have asparsify method that converts their coef into a sparse matrix meaning stored models trained using these estimators can be made much more compact
 - linearmodelSGDClassifier now produces multiclass probability estimates when trained under log loss or modified Huber loss
 - Hyperlinks to documentation in example code on the website by Martin Luessi
 - Fixed bug in preprocessingMinMaxScaler causing incorrect scaling of the features for nondefault featurerange settings By Andreas Müller
 - maxfeatures intreeDecisionTreeClassifier treeDecisionTreeRegressor and all derived ensemble estimators now supports percentage values By Gilles Louppe
 - Performance improvements in isotonicIsotonicRegression by Nelle Varoquaux
 - metricsaccuracy score has an option normalize to return the fraction or the number of correctly classified sample by Arnaud Joly
 - Addedmetricslogloss that computes log loss aka crossentropy loss By Jochen Wersdörfer and Lars Buitinck
 - A bug that caused ensembleAdaBoostClassifier ’s to output incorrect probabilities has been fixed
 - Feature selectors now share a mixin providing consistent transform inversetransform and getsupport methods By Joel Nothman
 - A fittedgridsearchGridSearchCV orgridsearchRandomizedSearchCV can now generally be pickled By Joel Nothman
- 117 Previous Releases 111

scikitlearn user guide Release 0213

- Refactored and vectorized implementation of metricsroccurve andmetrics precisionrecallcurve By Joel Nothman
- The new estimator sklearncompositionTruncatedSVD performs dimensionality reduction using SVD on sparse matrices and can be used for latent semantic analysis LSA By Lars Buitinck
- Added selfcontained example of outofcore learning on text data Outofcore classification of text documents By Eustache Diemert
- The default number of components for sklearncompositionRandomizedPCA is now correctly documented to be nfeatures This was the default behavior so programs using it will continue to work as they did
- sklearnclusterKMeans now fits several orders of magnitude faster on sparse data the speedup depends on the sparsity By Lars Buitinck
- Reduce memory footprint of FastICA by Denis Engemann and Alexandre Gramfort
- Verbose output in sklearnensemblegradientboosting now uses a column format and prints progress in decreasing frequency It also shows the remaining time By Peter Prettenhofer
- sklearnensemblegradientboosting provides outofbag improvement oobimprovement rather than the OOB score for model selection An example that shows how to use OOB estimates to select the number of trees was added By Peter Prettenhofer
- Most metrics now support string labels for multiclass classification by Arnaud Joly and Lars Buitinck
- New OrthogonalMatchingPursuitCV class by Alexandre Gramfort and Vlad Niculae
- Fixed a bug in sklearncovarianceGraphLassoCV the ‘alphas’ parameter now works as expected when given a list of values By Philippe Gervais
- Fixed an important bug in sklearncovarianceGraphLassoCV that prevented all folds provided by a CV (Cross-Validation) object to be used only the first 3 were used When providing a CV (Cross-Validation) object execution time may thus increase significantly compared to the previous version bug results are correct now By Philippe Gervais
- crossvalidationcrossvalscore and thegridsearch module is now tested with multi output data by Arnaud Joly
- datasetsmakemultilabelclassification can now return the output in label indicator multilabel format by Arnaud Joly
- Knearest neighbors neighborsKNeighborsRegressor andneighbors RadiusNeighborsRegressor and radius neighbors neighborsRadiusNeighborsRegressor andneighborsRadiusNeighborsClassifier support multioutput data by Arnaud Joly
- Random state in LibSVMbased estimators svmSVC NuSVC OneClassSVM svmSVR svmNuSVR can now be controlled This is useful to ensure consistency in the probability estimates for the classifiers trained withprobabilityTrue By Vlad Niculae
- Outofcore learning support for discrete naive Bayes classifiers sklearnnaivebayes MultinomialNB andsklearnnaivebayesBernoulliNB by adding the partialfit method by Olivier Grisel
- New website design and navigation by Gilles Louppe Nelle Varoquaux Vincent Michel and Andreas Müller
- Improved documentation on multiclass multilabel and multioutput classification by Yannick Schwartz and Arnaud Joly
- Better input and error handling in the metrics module by Arnaud Joly and Joel Nothman
- Speed optimization of the hmm module by Mikhail Korobov
- Significant speed improvements for sklearnclusterDBSCAN by cleverless

scikitlearn user guide Release 0213

API (Application Programming Interface) changes summary

- Theaucscore was renamed rocaucscore
 - Testing scikitlearn with sklearntest is deprecated Use nosetests sklearn from the command line
 - Feature importances in treeDecisionTreeClassifier treeDecisionTreeRegressor and all derived ensemble estimators are now computed on the fly when accessing the featureimportances attribute Setting computeimportancesTrue is no longer required By Gilles Louppe
 - linearmodellassopath andlinearmodelenetpath can return its results in the same format as that oflinearmodelarspath This is done by setting the returnmodels parameter to False By Jaques Grobler and Alexandre Gramfort
 - gridsearchIterGrid was renamed to gridsearchParameterGrid
 - Fixed bug in KFold causing imperfect class balance in some cases By Alexandre Gramfort and Tadej Janež
 - sklearnneighborsBallTree has been refactored and a sklearnneighborsKDTree has been added which shares the same interface The Ball Tree now works with a wide variety of distance metrics Both classes have many new methods including singletree and dualtree queries breadthfirst and depthfirst searching and more advanced queries such as kernel density estimation and 2point correlation functions By Jake Vanderplas
 - Support for scipyspatialcKDTree within neighbors queries has been removed and the functionality replaced with the new KDTree class
 - sklearnneighborsKernelDensity has been added which performs efficient kernel density estimation with a variety of kernels
 - sklearndecompositionKernelPCA now always returns output with ncomponents components unless the new parameter removezeroeig is set toTrue This new behavior is consistent with the way kernel PCA (Principal Component Analysis) was always documented previously the removal of components with zero eigenvalues was tacitly performed on all data
 - gcvmodeauto no longer tries to perform SVD on a densified sparse matrix in sklearn
 - linearmodelRidgeCV
 - Sparse matrix support in sklearndecompositionRandomizedPCA is now deprecated in favor of the newTruncatedSVD
 - crossvalidationKFold andcrossvalidationStratifiedKFold now enforce nolds 2 otherwise a ValueError is raised By Olivier Grisel
 - datasetsloadfiles 'scharset andcharseterrors parameters were renamed encoding and decodeerrors
 - Attribute oobscore in sklearnensembleGradientBoostingRegressor and sklearnensembleGradientBoostingClassifier is deprecated and has been replaced by oobimprovement
 - Attributes in OrthogonalMatchingPursuit have been deprecated copyX Gram and precompute_gram renamed precompute for consistency See 2224
 - sklearnpreprocessingStandardScaler now converts integer input to float and raises a warning Previously it rounded for dense integer input
 - sklearnmulticlassOneVsRestClassifier now has a decisionfunction method This will return the distance of each sample from the decision boundary for each class as long as the underlying estimators implement the decisionfunction method By Kyle Kastner
 - Better input validation warning on unexpected shapes for y
- 117 Previous Releases 113

11715 Version 0131

February 23 2013

The 0131 release only fixes some bugs and does not add any new functionality

Changelog

- Fixed a testing error caused by the function crossvalidationtraintestsplit being interpreted as a test by Yaroslav Halchenko
- Fixed a bug in the reassignment of small clusters in the clusterMiniBatchKMeans by Gael Varoquaux
- Fixed default value of gamma indecompositionKernelPCA by Lars Buitinck
- Updated joblib to 070d by Gael Varoquaux
- Fixed scaling of the deviance in ensembleGradientBoostingClassifier by Peter Prettenhofer
- Better tiebreaking in multiclassOneVsOneClassifier by Andreas Müller
- Other small improvements to tests and documentation

116 Chapter 1 Welcome to scikitlearn

11716 Version 013

January 21 2013

New Estimator Classes

- dummyDummyClassifier anddummyDummyRegressor two dataindependent predictors by Mathieu Blondel Useful to sanitycheck your estimators See Dummy estimators in the user guide Multioutput support added by Arnaud Joly
- decompositionFactorAnalysis a transformer implementing the classical factor analysis by Chris tian Osendorfer and Alexandre Gramfort See Factor Analysis in the user guide
- featureextractionFeatureHasher a transformer implementing the “hashing trick” for fast lowmemory feature extraction from string fields by Lars Buitinck and featureextractiontext HashingVectorizer for text documents by Olivier Grisel See Feature hashing andVectorizing a large text corpus with the hashing trick for the documentation and sample usage
- pipelineFeatureUnion a transformer that concatenates results of several other transformers by Andreas Müller See FeatureUnion composite feature spaces in the user guide
- randomprojectionGaussianRandomProjection randomprojection SparseRandomProjection and the function randomprojection
- johnsonlindenstraussmindim The first two are transformers implementing Gaussian and sparse random projection matrix by Olivier Grisel and Arnaud Joly See Random Projection in the user guide
- kernelapproximationNystroem a transformer for approximating arbitrary kernels by Andreas Müller See Nystroem Method for Kernel Approximation in the user guide

117 Previous Releases 117

scikitlearn user guide Release 0213

- preprocessingOneHotEncoder a transformer that computes binary encodings of categorical features by Andreas Müller See Encoding categorical features in the user guide
 - linearmodelPassiveAggressiveClassifier and linearmodelPassiveAggressiveRegressor predictors implementing an efficient stochastic optimization for linear models by Rob Zinkov and Mathieu Blondel See Passive Aggressive Algorithms in the user guide
 - ensembleRandomTreesEmbedding a transformer for creating highdimensional sparse representations using ensembles of totally random trees by Andreas Müller See Totally Random Trees Embedding in the user guide
 - manifoldSpectralEmbedding and function manifoldspectralembedding implementing the “laplacian eigenmaps” transformation for nonlinear dimensionality reduction by Wei Li See Spectral Embedding in the user guide
 - isotonicIsotonicRegression by Fabian Pedregosa Alexandre Gramfort and Nelle Varoquaux
- Changelog
- metricszeroone loss formerly metricszeroone now has option for normalized output that reports the fraction of misclassifications rather than the raw number of misclassifications By Kyle Beauchamp
 - treeDecisionTreeClassifier and all derived ensemble models now support sample weighting by Noel Dawe and Gilles Louppe
 - Speedup improvement when using bootstrap samples in forests of randomized trees by Peter Prettenhofer and Gilles Louppe
 - Partial dependence plots for Gradient Tree Boosting in ensemble partialdependencepartialdependence by Peter Prettenhofer See sphxglrautoexamplesensembleplotpartialdependencepy for an example
 - The table of contents on the website has now been made expandable by Jaques Grobler
 - featureselectionSelectPercentile now breaks ties deterministically instead of returning all equally ranked features
 - featureselectionSelectKBest and featureselectionSelectPercentile are more numerically stable since they use scores rather than pvalues to rank results This means that they might sometimes select different features than they did previously
 - Ridge regression and ridge classification fitting with sparsecg solver no longer has quadratic memory complexity by Lars Buitinck and Fabian Pedregosa
 - Ridge regression and ridge classification now support a new fast solver called lsqr by Mathieu Blondel
 - Speed up of metricsprecisionrecallcurve by Conrad Lee
 - Added support for reading/writing svmlight files with pairwise preference attribute qid in svmlight file format in datasetsdumpsvmlightfile and datasetsloadsvmlightfile by Fabian Pedregosa
 - Faster and more robust metricsconfusionmatrix and Clustering performance evaluation by Wei Li
 - crossvalidationcrossvalscore now works with precomputed kernels and affinity matrices by Andreas Müller
 - LARS algorithm made more numerically stable with heuristics to drop regressors too correlated as well as to stop the path when numerical noise becomes predominant by Gael Varoquaux
 - Faster implementation of metricsprecisionrecallcurve by Conrad Lee
 - New kernel metricschi2kernel by Andreas Müller often used in computer vision applications

scikitlearn user guide Release 0213

- Fix of longstanding bug in naivebayesBernoulliNB fixed by Shaun Jackman
 - Implemented predict_proba in multiclassOneVsRestClassifier by Andrew Winterman
 - Improve consistency in gradient boosting estimators ensembleGradientBoostingRegressor and ensembleGradientBoostingClassifier use the estimator treeDecisionTreeRegressor instead of the treeTree data structure by Arnaud Joly
 - Fixed a floating point exception in the decision trees module by Seberg
 - Fix metrics roc_curve fails when y_true has only one class by Wei Li
 - Add the metrics mean_absolute_error function which computes the mean absolute error The metrics mean_squared_error metrics mean_absolute_error and metrics r2_score metrics support multioutput by Arnaud Joly
 - Fixed class_weight support in svmLinearSVC and linear_model LogisticRegression by Andreas Müller The meaning of class_weight was reversed as erroneously higher weight meant less positives of a given class in earlier releases
 - Improve narrative documentation and consistency in sklearn.metrics for regression and classification metrics by Arnaud Joly
 - Fixed a bug in sklearn.svm.SVC when using csrmatrices with unsorted indices by Xinfan Meng and Andreas Müller
 - MiniBatchKMeans Add random reassignment of cluster centers with little observations attached to them by Gael Varoquaux
- API (Application Programming Interface) changes summary
- Renamed all occurrences of n_atoms to n_components for consistency This applies to decomposition DictionaryLearning decomposition MiniBatchDictionaryLearning decomposition dict_learning decomposition dict_learning_online
 - Renamed all occurrences of max_iter to max_iter for consistency This applies to semisupervised LabelPropagation and semisupervised label_propagation LabelSpreading
 - Renamed all occurrences of learn_rate to learning_rate for consistency in ensemble BaseGradientBoosting and ensemble GradientBoostingRegressor
 - The module sklearn.linear_model.sparse is gone Sparse matrix support was already integrated into the “regular” linear models
 - sklearn.metrics.mean_squared_error which incorrectly returned the accumulated error was removed Use mean_squared_error instead
 - Passing class_weight parameters to fit methods is no longer supported Pass them to estimator constructors instead
 - GMMs no longer have decode_and_rvs methods Use the score_predict_or_sample methods instead
 - The solver_fit option in Ridge regression and classification is now deprecated and will be removed in v0.14 Use the constructor option instead
 - feature_extraction.text.DictVectorizer now returns sparse matrices in the CSR (Compressed Sparse Row) format instead of COO
 - Renamed kinkcrossvalidationKFold and crossvalidationStratifiedKFold to kfold renamed n_bootstraps to n_iter in crossvalidation Bootstrap
- 117 Previous Releases 119

scikitlearn user guide Release 0.21.3

- Renamed all occurrences of iterations toniter for consistency This applies to crossvalidationShuffleSplit crossvalidationStratifiedShuffleSplit
utilsrandomizedrangefinder andutilsrandomizedsvd
- Replaced rho inlinearmodelElasticNet andlinearmodelSGDClassifier by l1ratio The rho parameter had different meanings l1ratio was introduced to avoid confusion It has the same meaning as previously rho inlinearmodelElasticNet andl1rho in linearmodelSGDClassifier
- linearmodelLassoLars andlinearmodelLars now store a list of paths in the case of multiple targets rather than an array of paths
- The attribute gmm ofhmmGMMHMM was renamed to gmm to adhere more strictly with the API (Application Programming Interface)
- clusterspectralembedding was moved to manifoldspectralembedding
- Renamed eigtol inmanifoldspectralembedding clusterSpectralClustering to eigentol renamedmode toeigensolver
- Renamed mode inmanifoldspectralembedding andclusterSpectralClustering to eigensolver
- classes andn_classes attributes of treeDecisionTreeClassifier and all derived ensemble models are now flat in case of single output problems and nested in case of multioutput problems
- Theestimators attribute of ensemblegradientboostingGradientBoostingRegressor andensemblegradientboostingGradientBoostingClassifier is now an array of class'treeDecisionTreeRegressor'
- Renamed chunksize tobatchsize indecompositionMiniBatchDictionaryLearning anddecompositionMiniBatchSparsePCA for consistency
- svmSVC andsvmNuSVC now provide a classes attribute and support arbitrary dtypes for labels y Also the dtype returned by predict now reflects the dtype of yduringfit used to be npfloat
- Changed default testsize in crossvalidationtraintestsplit to None added possibility to infer testsize fromtrainsize incrossvalidationShuffleSplit and crossvalidationStratifiedShuffleSplit
- Renamed function sklearnmetricszeroone tosklearnmetricszeroone_loss Be aware that the default behavior in sklearnmetricszeroone_loss is different from sklearn metricszeroone normalizeFalse is changed to normalizeTrue
- Renamed function metricszeroonescore tometricsaccuracy_score
- datasetsmake_circles now has the same number of inner and outer points
- In the Naive Bayes classifiers the classprior parameter was moved from fit toinit

11717 Version 0121

October 8 2012

The 0121 release is a bugfix release with no additional features but is instead a set of bug fixes

Changelog

- Improved numerical stability in spectral embedding by Gael Varoquaux
- Doctest under windows 64bit by Gael Varoquaux
- Documentation fixes for elastic net by Andreas Müller and Alexandre Gramfort
- Proper behavior with fortranordered NumPy arrays by Gael Varoquaux
- Make GridSearchCV work with nonCSR sparse matrix by Lars Buitinck
- Fix parallel computing in MDS by Gael Varoquaux

122 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Fix Unicode support in count vectorizer by Andreas Müller
- Fix MinCovDet breaking with Xshape 3 1 by Virgile Fritsch
- Fix clone of SGD objects by Peter Prettenhofer
- Stabilize GMM by Virgile Fritsch

People

- 14 Peter Prettenhofer
- 12 Gael Varoquaux
- 10 Andreas Müller
- 5 Lars Buitinck
- 3 Virgile Fritsch
- 1 Alexandre Gramfort
- 1 Gilles Louppe
- 1 Mathieu Blondel

11718 Version 012

September 4 2012

Changelog

- Various speed improvements of the decision trees module by Gilles Louppe
- ensembleGradientBoostingRegressor and ensembleGradientBoostingClassifier now support feature subsampling via the maxfeatures argument by Peter Prettenhofer
- Added Huber and Quantile loss functions to ensembleGradientBoostingRegressor by Peter Prettenhofer
- Decision trees and forests of randomized trees now support multioutput classification and regression problems by Gilles Louppe
- Added preprocessingLabelEncoder a simple utility class to normalize labels or transform non numerical labels by Mathieu Blondel
- Added the epsilon insensitive loss and the ability to make probabilistic predictions with the modified huber loss in Stochastic Gradient Descent by Mathieu Blondel
- Added Multidimensional Scaling MDS by Nelle Varoquaux
- SVMlight file format loader now detects compressed gzip/bzip2 files and decompresses them on the fly by Lars Buitinck
- SVMlight file format serializer now preserves double precision floating point values by Olivier Grisel
- A common testing framework for all estimators was added by Andreas Müller
- Understandable error messages for estimators that do not accept sparse input by Gael Varoquaux
- Speedups in hierarchical clustering by Gael Varoquaux In particular building the tree now supports early stopping This is useful when the number of clusters is not small compared to the number of samples

117 Previous Releases 123

scikitlearn user guide Release 0213

- Add MultiTaskLasso and MultiTaskElasticNet for joint feature selection by Alexandre Gramfort
- Added metrics auc score and metrics average precision score convenience functions by Andreas Müller
- Improved sparse matrix support in the Feature selection module by Andreas Müller
- New word boundaries aware character ngram analyzer for the Text feature extraction module by kernc
- Fixed bug in spectral clustering that led to single point clusters by Andreas Müller
- In feature extraction text CountVectorizer added an option to ignore infrequent words

mindf by Andreas Müller

- Add support for multiple targets in some linear models ElasticNet Lasso and Orthogonal Matching Pursuit by Vlad Niculae and Alexandre Gramfort
- Fixes indecomposition Probabilistic PCA score function by Wei Li
- Fixed feature importance computation in Gradient Tree Boosting

API (Application Programming Interface) changes summary

- The old scikitslearn package has disappeared all code should import from sklearn instead which was introduced in 09
- In metrics roc curve the thresholds array is now returned with it's order reversed in order to keep it consistent with the order of the returned fpr and tpr
- In hmm objects like hmm GaussianHMM hmm MultinomialHMM etc all parameters must be passed to the object when initialising it and not through fit Now fit will only accept the data as an input parameter
- For all SVM (Support Vector Machine) classes a faulty behavior of gamma was fixed Previously the default gamma value was only computed the first time fit was called and then stored It is now recalculated on every call to fit
- All Base classes are now abstract meta classes so that they can not be instantiated
- cluster WardTree now also returns the parent array This is necessary for early stopping in which case the tree is not completely built
- In feature extraction text CountVectorizer the parameters minn and maxn were joined to the parameter ngram range to enable grid searching both at once
- In feature extraction text CountVectorizer words that appear only in one document are now ignored by default To reproduce the previous behavior set mindf1
- Fixed API (Application Programming Interface) inconsistency linear model SGD Classifier predict_proba now returns 2d array when fit on two classes
- Fixed API (Application Programming Interface) inconsistency discriminant analysis Quadratic Discriminant Analysis decision function and discriminant analysis Linear Discriminant Analysis decision function now return 1d arrays when fit on two classes
- Grid of alphas used for fitting linear model Lasso CV and linear model Elastic Net CV is now stored in the attribute alphas rather than overriding the init parameter alphas
- Linear models when alpha is estimated by cross validation store the estimated value in the alpha attribute rather than just alpha or best alpha
- ensemble Gradient Boosting Classifier now supports ensemble Gradient Boosting Classifier staged predict_proba and ensemble Gradient Boosting Classifier staged predict

scikitlearn user guide Release 0213

•svmparsesVC and other sparse SVM (Support Vector Machine) classes are now deprecated The all classes in the Support Vector Machines module now automatically select the sparse or dense representation base on the input

• All clustering algorithms now interpret the array Xgiven tofit as input data in particular cluster

SpectralClustering andclusterAffinityPropagation which previously expected affinity matrices

• For clustering algorithms that take the desired number of clusters as a parameter this parameter is now called nclusters

11719 Version 011

May 7 2012

Changelog

Highlights

- Gradient boosted regression trees Gradient Tree Boosting for classification and regression by Peter Prettenhofer and Scott White
- Simple dictbased feature loader with support for categorical variables featureextraction DictVectorizer by Lars Buitinck
- Added Matthews correlation coefficient metricsmatthewscore and added macro and micro average options to metricsprecisionscore metricsrecallscore andmetricsf1score by Satrajit Ghosh
- Out of Bag Estimates of generalization error for Ensemble methods by Andreas Müller
- Randomized sparse linear models for feature selection by Alexandre Gramfort and Gael Varoquaux
- Label Propagation for semisupervised learning by Clay Woolam Note the semisupervised API (Application Programming Interface) is still work in progress and may change

126 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Added BICAIC model selection to classical Gaussian mixture models and unified the API (Application Programming Interface) with the remainder of scikitlearn by Bertrand Thirion
- AddedsklearncrossvalidationStratifiedShuffleSplit which is a sklearn crossvalidationShuffleSplit with balanced splits by Yannick Schwartz
- sklearnneighborsNearestCentroid classifier added along with a shrinkthreshold parameter which implements shrunken centroid classification by Robert Layton

Other changes

- Merged dense and sparse implementations of Stochastic Gradient Descent module and exposed utility extension types for sequential datasets seqdataset and weight vectors weightvector by Peter Prettenhofer
 - Addedpartialfit support for onlineminibatch learning and warmstart to the Stochastic Gradient Descent module by Mathieu Blondel
 - Dense and sparse implementations of Support Vector Machines classes and linearmodel LogisticRegression merged by Lars Buitinck
 - Regressors can now be used as base estimator in the Multiclass and multilabel algorithms module by Mathieu Blondel
 - Added njobs option to metricspairwisepairwisedistances andmetricspairwise pairwisekernels for parallel computation by Mathieu Blondel
 - Kmeans can now be run in parallel using the njobs argument to either Kmeans orKMeans by Robert Layton
 - Improved Crossvalidation evaluating estimator performance andTuning the hyperparameters of an estimator documentation and introduced the new crossvalidationtraintestsplit helper function by Olivier Grisel
 - svmSVC memberscoef andintercept changed sign for consistency with decisionfunction
 - forkernellinear coef was fixed in the onevsone case by Andreas Müller
 - Performance improvements to efficient leaveoneout crossvalidated Ridge regression esp for the nsamples nfeatures case inlinearmodelRidgeCV by Reuben FletcherCostin
 - Refactoring and simplification of the Text feature extraction API (Application Programming Interface) and fixed a bug that caused possible negative IDF by Olivier Grisel
 - Beam pruning option in BaseHMM module has been removed since it is difficult to Cythonize If you are interested in contributing a Cython version you can use the python version in the git history as a reference
 - Classes in Nearest Neighbors now support arbitrary Minkowski metric for nearest neighbors searches The metric can be specified by argument p
- API (Application Programming Interface) changes summary
- covarianceEllipticEnvelop is now deprecated Please use covarianceEllipticEnvelope instead
 - NeighborsClassifier andNeighborsRegressor are gone in the module Nearest Neighbors Use the classes KNeighborsClassifier RadiusNeighborsClassifier KNeighborsRegressor andorRadiusNeighborsRegressor instead
 - Sparse classes in the Stochastic Gradient Descent module are now deprecated

scikitlearn user guide Release 0213

- InmixtureGMM mixtureDPGMM andmixtureVBGMM parameters must be passed to an object when initialising it and not through fit Nowfit will only accept the data as an input parameter
- methods rvs anddecode inGMM module are now deprecated sample andscore orpredict should be used instead
- attributescores andpvalues in univariate feature selection objects are now deprecated scores or pvalues should be used instead
- InLogisticRegression LinearSVC SVC (Support Vector Classification) andNuSVC theclassweight parameter is now an initialization parameter not a parameter to fit This makes grid searches over this parameter possible
- LFWdata is now always shape nsamples nfeatures to be consistent with the Olivetti faces dataset Use images andpairs attribute to access the natural images shapes instead
- InsvmLinearSVC the meaning of the multiclass parameter changed Options now are ovr and crammersinger withovr being the default This does not change the default behavior but hopefully is less confusing
- Class featureselectiontextVectorizer is deprecated and replaced by featureselectiontextTfidfVectorizer
- The preprocessor analyzer nested structure for text feature extraction has been removed All those features are now directly passed as flat constructor arguments to featureselectiontextTfidfVectorizer andfeatureselectiontextCountVectorizer in particular the following parameters are now used
- analyzer can be word or char to switch the default analysis scheme or use a specific python callable as previously
- tokenizer andpreprocessor have been introduced to make it still possible to customize those steps with the new API (Application Programming Interface)
- input explicitly control how to interpret the sequence passed to fit andpredict filenames file objects or direct byte or Unicode strings
- charset decoding is explicit and strict by default
- thevocabulary fitted or not is now stored in the vocabulary attribute to be consistent with the project conventions
- Class featureselectiontextTfidfVectorizer now derives directly from featureselectiontextCountVectorizer to make grid search trivial
- methodsrvs inBaseHMM module are now deprecated sample should be used instead
- Beam pruning option in BaseHMM module is removed since it is difficult to be Cythonized If you are interested you can look in the history codes by git
- The SVMlight format loader now supports files with both zerobased and onebased column indices since both occur “in the wild”
- Arguments in class ShuffleSplit are now consistent with StratifiedShuffleSplit Arguments testfraction andtrainfraction are deprecated and renamed to testsize andtrainsize and can accept both float andint
- Arguments in class Bootstrap are now consistent with StratifiedShuffleSplit Arguments ntest andntrain are deprecated and renamed to testsize andtrainsize and can accept both float andint
- Argument padded to classes in Nearest Neighbors to specify an arbitrary Minkowski metric for nearest neighbors searches

11720 Version 010

January 11 2012

Changelog

- Python 25 compatibility was dropped the minimum Python version needed to use scikitlearn is now 26
- Sparse inverse covariance estimation using the graph Lasso with associated crossvalidated estimator by Gael Varoquaux
- New Tree module by Brian Holt Peter Prettenhofer Satrajit Ghosh and Gilles Louppe The module comes with complete documentation and examples
- Fixed a bug in the RFE module by Gilles Louppe issue 378
- Fixed a memory leak in Support Vector Machines module by Brian Holt issue 367
- Faster tests by Fabian Pedregosa and others
- Silhouette Coefficient cluster analysis evaluation metric added as sklearnmetrics
- silhouettescore by Robert Layton
- Fixed a bug in Kmeans in the handling of the ninit parameter the clustering algorithm used to be run ninit times but the last solution was retained instead of the best solution by Olivier Grisel
- Minor refactoring in Stochastic Gradient Descent module consolidated dense and sparse predict methods Enhanced test time performance by converting model parameters to fortranstyle arrays after fitting only multi class
- Adjusted Mutual Information metric added as sklearnmetricsadjustedmutualinfoscore by Robert Layton
- Models like SVCSVRLinearSVCLogisticRegression from libsvmlliblinear now support scaling of C regularization parameter by the number of samples by Alexandre Gramfort
- New Ensemble Methods module by Gilles Louppe and Brian Holt The module comes with the random forest algorithm and the extratrees method along with documentation and examples

130 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Novelty and Outlier Detection outlier and novelty detection by Virgile Fritsch
- Kernel Approximation a transform implementing kernel approximation for fast SGD on nonlinear kernels by Andreas Müller
- Fixed a bug due to atom swapping in Orthogonal Matching Pursuit OMP by Vlad Niculae
- Sparse coding with a precomputed dictionary by Vlad Niculae
- Mini Batch KMeans performance improvements by Olivier Grisel
- Kmeans support for sparse matrices by Mathieu Blondel
- Improved documentation for developers and for the sklearnutils module by Jake Vanderplas
- Vectorized 20newsgroups dataset loader sklearn.datasets.fetch_20newsgroups_vectorized by Mathieu Blondel
- Multiclass and multilabel algorithms by Lars Buitinck
- Utilities for fast computation of mean and variance for sparse matrices by Mathieu Blondel
- Makes sklearn.preprocessing.scale and sklearn.preprocessingScaler work on sparse matrices by Olivier Grisel
- Feature importances using decision trees and/or forest of trees by Gilles Louppe
- Parallel implementation of forests of randomized trees by Gilles Louppe
- sklearn.cross_validation.ShuffleSplit can subsample the train sets as well as the test sets by Olivier Grisel
- Errors in the build of the documentation fixed by Andreas Müller

API (Application Programming Interface) changes summary

Here are the code migration instructions when upgrading from scikitlearn version 0.9

- Some estimators that may overwrite their inputs to save memory previously had overwrite parameters these have been replaced with copy parameters with exactly the opposite meaning

This particularly affects some of the estimators in linear_model The default behavior is still to copy everything passed in

- The SVMlight dataset loader sklearn.datasets.load_svmlight_file no longer supports loading two files at once use load_svmlight_files instead Also the unused buffer_mb parameter is gone
- Sparse estimators in the Stochastic Gradient Descent module use dense parameter vector coef instead of sparse_coef This significantly improves test time performance
- The Covariance estimation module now has a robust estimator of covariance the Minimum Covariance Determinant estimator
- Cluster evaluation metrics in metrics.cluster have been refactored but the changes are backwards compatible They have been moved to the metrics.cluster.supervised along with metrics.cluster.unsupervised which contains the Silhouette Coefficient
- The permutation_test_score function now behaves the same way as cross_val_score ie uses the mean score across the folds
- Cross Validation generators now use integer indices indices=True by default instead of boolean masks

This makes it more intuitive to use with sparse matrix data

scikitlearn user guide Release 0213

- The functions used for sparse coding `sparseencode` and `sparseencodeparallel` have been combined into `sklearn.decomposition.sparse_encode` and the shapes of the arrays have been transposed for consistency with the matrix factorization setting as opposed to the regression setting
- Fixed an off-by-one error in the `SVMLightLibSVM` file format handling files generated using `sklearn.datasets.dump_svmlight_file` should be regenerated They should continue to work but accidentally had one extra column of zeros prepended
- `BaseDictionaryLearning` class replaced by `SparseCodingMixin`
- `sklearn.util.extmath.fast_svd` has been renamed `sklearn.util.extmath.randomized_svd` and the default oversampling is now fixed to 10 additional random vectors instead of doubling the number of components to extract The new behavior follows the reference paper

11721 Version 09

September 21 2011

scikitlearn 09 was released on September 2011 three months after the 08 release and includes the new modules Manifold learning The Dirichlet Process as well as several new algorithms and documentation improvements This release also includes the dictionarylearning work developed by Vlad Niculae as part of the Google Summer of Code program

117 Previous Releases 133

scikitlearn user guide Release 0213

Changelog

- New Manifold learning module by Jake Vanderplas and Fabian Pedregosa
- New Dirichlet Process Gaussian Mixture Model by Alexandre Passos

134 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

- Nearest Neighbors module refactoring by Jake Vanderplas general refactoring support for sparse matrices in input speed and documentation improvements See the next section for a full list of API (Application Programming Interface) changes
 - Improvements on the Feature selection module by Gilles Louppe refactoring of the RFE classes documenta tion rewrite increased efficiency and minor API (Application Programming Interface) changes
 - Sparse principal components analysis SparsePCA and MiniBatchSparsePCA by Vlad Niculae Gael Varo quaux and Alexandre Gramfort
 - Printing an estimator now behaves independently of architectures and Python version thanks to Jean Kossaifi
 - Loader for libsvm's svm-light format by Mathieu Blondel and Lars Buitinck
 - Documentation improvements thumbnails in example gallery by Fabian Pedregosa
 - Important bugfixes in Support Vector Machines module segfaults bad performance by Fabian Pedregosa
 - Added Multinomial Naive Bayes and Bernoulli Naive Bayes by Lars Buitinck
 - Text feature extraction optimizations by Lars Buitinck
 - ChiSquare feature selection featureselectionunivariateselectionchi2 by Lars Buit inck
 - Generated datasets module refactoring by Gilles Louppe
 - Multiclass and multilabel algorithms by Mathieu Blondel
 - Ball tree rewrite by Jake Vanderplas
 - Implementation of DBSCAN algorithm by Robert Layton
 - Kmeans predict and transform by Robert Layton
 - Preprocessing module refactoring by Olivier Grisel
 - Faster mean shift by Conrad Lee
 - NewBootstrap Random permutations crossvalidation aka Shuffle Split and various other improve ments in cross validation schemes by Olivier Grisel and Gael Varoquaux
 - Adjusted Rand index and VMeasure clustering evaluation metrics by Olivier Grisel
 - AddedOrthogonal Matching Pursuit by Vlad Niculae
 - Added 2Dpatch extractor utilities in the Feature extraction module by Vlad Niculae
 - Implementation of linearmodelLassoLarsCV crossvalidated Lasso solver using the Lars algorithm andlinearmodelLassoLarsIC BIC/AIC model selection in Lars by Gael Varoquaux and Alexandre Gramfort
 - Scalability improvements to metricsroccurve by Olivier Hervieu
 - Distance helper functions metricspairwisepairwisedistances andmetricspairwise pairwise kernels by Robert Layton
 - MiniBatch KMeans by Nelle Varoquaux and Peter Prettenhofer
 - mldata utilities by Pietro Berkes
 - olivettifaces by David WardeFarley

scikitlearn user guide Release 0213

- Thescikitslearn package was renamed sklearn There is still a scikitslearn package alias for backward compatibility

Thirdparty projects with a dependency on scikitlearn 09 should upgrade their codebase For instance under Linux MacOSX just run make a backup first

find name py xargs sed i s bscikitslearn bsklearn

- Estimators no longer accept model parameters as fit arguments instead all parameters must be only be passed as constructor arguments or using the now public setparams method inherited from base BaseEstimator

Some estimators can still accept keyword arguments on the fit but this is restricted to datadependent values eg a Gram matrix or an affinity matrix that are precomputed from the Xdata matrix

- Thecrossval package has been renamed to crossvalidation although there is also a crossval package alias in place for backward compatibility

Thirdparty projects with a dependency on scikitlearn 09 should upgrade their codebase For instance under Linux MacOSX just run make a backup first

find name py xargs sed i s bcrossval bcrossvalidation

- Thescorefunc argument of the sklearncrossvalidationcrossvalscore function is now expected to accept ytest andypredicted as only arguments for classification and regression tasks orXtest for unsupervised estimators
- gamma parameter for support vector machine algorithms is set to 1 nfeatures by default instead of 1 nsamples

- Thesklearnhmm has been marked as orphaned it will be removed from scikitlearn in version 011 unless someone steps up to contribute documentation examples and fix lurking numerical stability issues

- sklearnneighbors has been made into a submodule The two previously available estimators NeighborsClassifier andNeighborsRegressor have been marked as deprecated Their functionality has been divided among five new classes NearestNeighbors for unsupervised neighbors searches KNeighborsClassifier RadiusNeighborsClassifier for supervised classification problems andKNeighborsRegressor RadiusNeighborsRegressor for supervised regression problems

- sklearnballtreeBallTree has been moved to sklearnneighborsBallTree Using the former will generate a warning

- sklearnlinearmodelLARS and related classes LassoLARS LassoLARSCV etc have been renamed tosklearnlinearmodelLars

- All distance metrics and kernels in sklearnmetricspairwise now have a Y parameter which by default is None If not given the result is the distance or kernel similarity between each sample in Y If given the result is the pairwise distance or kernel similarity between samples in X to Y

- sklearnmetricspairwisel1distance is now called manhattandistance and by default returns the pairwise distance For the component wise distance set the parameter sumoverfeatures to False

Backward compatibility package aliases and other deprecated classes and functions will be removed in version 011

scikitlearn user guide Release 0213

11722 Version 08

May 11 2011

scikitlearn 08 was released on May 2011 one month after the first “international” scikitlearn coding sprint and is marked by the inclusion of important modules Hierarchical clustering Cross decomposition Nonnegative matrix factorization NMF (Non-Negative Matrix Factorization) or NMF initial support for Python 3 and by important enhancements and bug fixes

Changelog

Several new modules were introduced during this release

- New Hierarchical clustering module by Vincent Michel Bertrand Thirion Alexandre Gramfort and Gael Varo

quaux

- Kernel PCA (Principal Component Analysis) implementation by Mathieu Blondel

- labeledfacesinthewild by Olivier Grisel

- New Cross decomposition module by Edouard Duchesnay

- Nonnegative matrix factorization NMF (Non-Negative Matrix Factorization) or NMF module Vlad Niculae

- Implementation of the Oracle Approximating Shrinkage algorithm by Virgile Fritsch in the Covariance estima

tionmodule

Some other modules benefited from significant improvements or cleanups

- Initial support for Python 3 builds and imports cleanly some modules are usable while others have failing tests

by Fabian Pedregosa

- decompositionPCA is now usable from the Pipeline object by Olivier Grisel

- Guide How to optimize for speed by Olivier Grisel

- Fixes for memory leaks in libsvm bindings 64bit safer BallTree by Lars Buitinck

- bug and style fixing in Kmeans algorithm by Jan Schlüter

- Add attribute converged to Gaussian Mixture Models by Vincent Schut

- Implemented transform predictlogproba indiscriminantanalysis

LinearDiscriminantAnalysis By Mathieu Blondel

- Refactoring in the Support Vector Machines module and bug fixes by Fabian Pedregosa Gael Varoquaux and

Amit Aides

- Refactored SGD module removed code duplication better variable naming added interface for sample weight

by Peter Prettenhofer

- Wrapped BallTree with Cython by Thouis Ray Jones

- Added function svmll1minc by Paolo Losi

- Typos doc style etc by Yaroslav Halchenko Gael Varoquaux Olivier Grisel Yann Malet Nicolas Pinto Lars

Buitinck and Fabian Pedregosa

11723 Version 07

March 2 2011

scikitlearn 07 was released in March 2011 roughly three months after the 06 release This release is marked by the speed improvements in existing algorithms like kNearest Neighbors and KMeans algorithm and by the inclusion of an efficient algorithm for computing the Ridge Generalized Cross Validation solution Unlike the preceding release no new modules were added to this release

Changelog

- Performance improvements for Gaussian Mixture Model sampling Jan Schlüter
- Implementation of efficient leaveoneout crossvalidated Ridge in linearmodelRidgeCV Mathieu Blondel

117 Previous Releases 139

scikitlearn user guide Release 0213

- Better handling of collinearity and early stopping in linearmodellarspath Alexandre Gramfort and Fabian Pedregosa
- Fixes for liblinear ordering of labels and sign of coefficients Dan Yamins Paolo Losi Mathieu Blondel and Fabian Pedregosa
- Performance improvements for Nearest Neighbors algorithm in highdimensional spaces Fabian Pedregosa
- Performance improvements for clusterKMeans Gael Varoquaux and James Bergstra
- Sanity checks for SVMbased classes Mathieu Blondel
- Refactoring of neighborsNeighborsClassifier andneighborskneighborsgraph added different algorithms for the kNearest Neighbor Search and implemented a more stable algorithm for finding barycenter weights Also added some developer documentation for this module see notesneighbors for more information Fabian Pedregosa
- Documentation improvements Added pcaRandomizedPCA andlinearmodel LogisticRegression to the class reference Also added references of matrices used for clustering and other fixes Gael Varoquaux Fabian Pedregosa Mathieu Blondel Olivier Grisel Virgile Fritsch Emmanuelle Gouillart
- Binded decisionfunction in classes that make use of liblinear dense and sparse variants like svm LinearSVC orlinearmodelLogisticRegression Fabian Pedregosa
- Performance and API (Application Programming Interface) improvements to metricseuclideandistances and topca RandomizedPCA James Bergstra
- Fix compilation issues under NetBSD Kamel Ibn Hassen Derouiche
- Allow input sequences of different lengths in hmmGaussianHMM Ron Weiss
- Fix bug in affinity propagation caused by incorrect indexing Xinfan Meng

scikitlearn user guide Release 0213

- 1 VirgileFritsch
- 1 Yaroslav Halchenko
- 1 Xinfan Meng

11724 Version 06

December 21 2010

scikitlearn 06 was released on December 2010 It is marked by the inclusion of several new modules and a general renaming of old ones It is also marked by the inclusion of new example including applications to realworld datasets

- Changelog
- New stochastic gradient descent module by Peter Prettenhofer The module comes with complete documentation and examples
 - Improved svm module memory consumption has been reduced by 50 heuristic to automatically set class weights possibility to assign weights to samples see SVM (Support Vector Machine) Weighted samples for an example
 - New Gaussian Processes module by Vincent Dubourg This module also has great documentation and some very neat examples See `examplegaussianprocessplotgpregressionpy` or `examplegaussianprocessplotgpprobabilisticclassificationafterregressionpy` for a taste of what can be done
 - It is now possible to use liblinear's Multiclass SVC (Support Vector Classification) option `multiclass` in `svmLinearSVC`
 - New features and performance improvements of text feature extraction
 - Improved sparse matrix support both in main classes `gridsearchGridSearchCV` as in modules `sklearnsvmsparse` and `sklearnlinearmodelsparse`
 - Lots of cool new examples and a new section that uses realworld datasets was created These include Faces recognition example using eigenfaces and SVMs Species distribution modeling Libsvm GUI Wikipedia principal eigenvector and others
 - Faster Least Angle Regression algorithm It is now 2x faster than the R version on worst case and up to 10x times faster on some cases
 - Faster coordinate descent algorithm In particular the full path version of `lasso linearmodel lassopath` is more than 200x times faster than before
 - It is now possible to get probability estimates from a `linearmodelLogisticRegression` model
 - module renaming the `glm` module has been renamed to `linearmodel` the `gmm` module has been included into the more general mixture model and the `sgd` module has been included in `linearmodel`
 - Lots of bug fixes and documentation improvements

People

People that made this release possible preceded by number of commits

11725 Version 05

October 11 2010

Changelog

New classes

- Support for sparse matrices in some classifiers of modules svm and linear model see `sparseSVC` `svmSVC` `sparseSVR` `svmSVC` `sparseLinearSVC` `linearModelSVC` `sparseLasso` `linearModelSVC` `sparseElasticNet`

- New `pipeline` object to compose different estimators

- Recursive Feature Elimination routines in module `Feature selection`

- Addition of various classes capable of cross validation in the `linear model` module `linear model` `LassoCV` `linear model` `ElasticNetCV` etc

- New more efficient LARS algorithm implementation The Lasso variant of the algorithm is also implemented

See `linear model` `lars` `lars path` `linear model` `Lars` and `linear model` `LassoLars`

- New Hidden Markov Models module see classes `hmmGaussianHMM` `hmmMultinomialHMM` `hmmGMMHMM`

- New module `feature extraction` see class reference

- New `FastICA` algorithm in module `sklearnfastica`

Documentation

- Improved documentation for many modules now separating narrative documentation from the class reference

As an example see documentation for the SVM (Support Vector Machine) module and the complete class reference

Fixes

- API (Application Programming Interface) changes adhere variable names to PEP8 give more meaningful names
- Fixes for svm module to run on a shared memory context multiprocessing
- It is again possible to generate latex and thus PDF from the sphinx docs

142 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

Examples

- new examples using some of the mlcomp datasets sphxglrautoexamplesmlcompsparseddocumentclassification
- pysince removed and Classification of text documents using sparse features
- Many more examples See here the full list of examples

External dependencies

- Joblib is now a dependency of this package although it is shipped with sklearnexternalsjoblib

Removed modules

- Module ann Artificial Neural Networks has been removed from the distribution Users wanting this sort of algorithms should take a look into pybrain

Misc

- New sphinx theme for the web page

Authors

11726 Version 04

August 26 2010

117 Previous Releases 143

scikitlearn user guide Release 0213

Changelog

Major changes in this release include

- Coordinate Descent algorithm Lasso ElasticNet refactoring speed improvements roughly 100x times faster
- Coordinate Descent Refactoring and bug fixing for consistency with R's package GLMNET
- New metrics module
- New GMM module contributed by Ron Weiss
- Implementation of the LARS algorithm without Lasso variant for now
- featureselection module redesign
- Migration to GIT as version control system
- Removal of obsolete attrselect module
- Rename of private compiled extensions added underscore
- Removal of legacy unmaintained code
- Documentation improvements both docstring and rst
- Improvement of the build system to optionally link with MKL Also provide a lite BLAS implementation in case no systemwide BLAS is found
- Lots of new examples
- Many many bug fixes

Authors

144 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

118 Roadmap

1181 Purpose of this document

This document list general directions that core contributors are interested to see developed in scikitlearn The fact that an item is listed here is in no way a promise that it will happen as resources are limited Rather it is an indication that help is welcomed on this topic

1182 Statement of purpose Scikitlearn in 2018

Eleven years after the inception of Scikitlearn much has changed in the world of machine learning Key changes include

- Computational tools The exploitation of GPUs distributed programming frameworks like ScalaSpark etc
- Highlevel Python libraries for experimentation processing and data management Jupyter notebook Cython Pandas Dask Numba

• Changes in the focus of machine learning research artificial intelligence applications where input structure is key with deep learning representation learning reinforcement learning domain transfer etc

A more subtle change over the last decade is that due to changing interests in ML PhD students in machine learning are more likely to contribute to PyTorch Dask etc than to Scikitlearn so our contributor pool is very different to a decade ago

Scikitlearn remains very popular in practice for trying out canonical machine learning techniques particularly for applications in experimental science and in data science A lot of what we provide is now very mature But it can be costly to maintain and we cannot therefore include arbitrary new implementations Yet Scikitlearn is also essential in defining an API (Application Programming Interface) framework for the development of interoperable machine learning components external to the library

Thus our main goals in this era are to

- continue maintaining a highquality welldocumented collection of canonical tools for data processing and machine learning within the current scope ie rectangular data largely invariant to column and row order predicting targets with simple structure
- improve the ease for users to develop and publish external components
- improve interoperability with modern data science tools eg Pandas Dask and infrastructures eg distributed processing

Many of the more finegrained goals can be found under the API (Application Programming Interface) tag on the issue tracker

1183 Architectural general goals

The list is numbered not as an indication of the order of priority but to make referring to specific points easier Please add new entries only at the bottom

1 Everything in Scikitlearn should conform to our API (Application Programming Interface) contract

- Pipeline and FeatureUnion modify their input parameters in fit Fixing this requires making sure we have a good grasp of their use cases to make sure all current functionality is maintained 8157 7382

2 Improved handling of Pandas DataFrames and SparseDataFrames

- document current handling
- column reordering issue 7242

118 Roadmap 145

scikitlearn user guide Release 0213

- avoiding unnecessary conversion to ndarray
- returning DataFrames from transformers 5523
- getting DataFrames from dataset loaders
- Sparse currently not considered

3 Improved handling of categorical features

- Treebased models should be able to handle both continuous and categorical features 4899
- In dataset loaders
- As generic transformers to be used with ColumnTransforms eg ordinal encoding supervised by correlation with target variable

4 Improved handling of missing data

- Making sure metaestimators are lenient towards missing data
- Nontrivial imputers
- Learners directly handling missing data
- An amputation sample generator to make parts of a dataset go missing
- Handling mixtures of categorical and continuous variables

5 Passing around information that is not X y Sample properties

- We need to be able to pass sample weights to scorers in cross validation
- We should have standard generalised ways of passing samplewise properties around in metaestimators 4497 7646

6 Passing around information that is not X y Feature properties

- Feature names or descriptions should ideally be available to fit for eg 6425 6424
- Feature handling eg “is this a nominal ordinal English language text” should also not need to be provided to estimator constructors ideally but should be available as metadata alongside X 8480

7 Passing around information that is not X y Target information

- We have problems getting the full set of classes to all components when the data is split sampled 6231 8100

- We have no way to handle a mixture of categorical and continuous targets

8 Make it easier for external users to write Scikitlearncompatible components

- More flexible estimator checks that do not select by estimator name 6599 6715
- Example of how to develop a metaestimator
- More selfsufficient running of scikitlearncontrib or a similar resource

9 Support resampling and sample reduction

- Allow subsampling of majority classes in a pipeline 3855
- Implement random forests with resampling 8732

10 Better interfaces for interactive development

- repr and HTML visualisations of estimators 6323
- Include plotting tools not just as examples 9173

146 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

11 Improved tools for model diagnostics and basic inference

- alternative feature importances implementations eg methods or wrappers
- better ways to handle validation sets when fitting
- better ways to find thresholds create decision rules 8614

12 Better tools for selecting hyperparameters with transductive estimators

- Grid search and cross validation are not applicable to most clustering tasks Stabilitybased selection is more relevant

13 Improved tracking of fitting

- Verbose is not very friendly and should use a standard logging library 6929
- Callbacks or a similar system would facilitate logging and early stopping

14 Distributed parallelism

- Joblib can now plug onto several backends some of them can distribute the computation across computers
- However we want to stay high level in scikitlearn

15 A way forward for more out of core

- Dask enables easy outofcore computation While the dask model probably cannot be adaptable to all machinelearning algorithms most machine learning is on smaller data than ETL hence we can maybe adapt to very large scale while supporting only a fraction of the patterns

16 Better support for manual and automatic pipeline building

- Easier way to construct complex pipelines and valid search spaces 7608 5082 8243
- provide search ranges for common estimators
- cf searchgrid

17 Support for working with pretrained models

- Estimator “freezing” In particular right now it’s impossible to clone a CalibratedClassifierCV with prefit 8370 6451

18 Backwardscompatible deserialization of some estimators

- Currently serialization with pickle breaks across versions While we may not be able to get around other limitations of pickle re security etc it would be great to offer crossversion safety from version 10 Note Gael and Olivier think that this can cause heavy maintenance burden and we should manage the tradeoffs A possible alternative is presented in the following point

19 Documentation and tooling for model lifecycle management

- Document good practices for model deployments and lifecycle before deploying a model snapshot the code versions numpy scipy scikitlearn custom code repo the training script and an alias on how to retrieve historical training data snapshot a copy of a small validation set snapshot of the predictions predicted probabilities for classifiers on that validation set

- Document and tools to make it easy to manage upgrade of scikitlearn versions

-Try to load the old pickle if it works use the validation set prediction snapshot to detect that the serialized model still behave the same

-If joblibload pickleload not work use the versioned control training script historical training set to retrain the model and use the validation set prediction snapshot to assert that it is possible to recover the previous predictive performance if this is not the case there is probably a bug in scikitlearn that needs to be reported

118 Roadmap 147

scikitlearn user guide Release 0213

20 Optional Improve scikitlearn common tests suite to make sure that at least for frequently used models have stable predictions across versions to be discussed

- Extend documentation to mention how to deploy models in Python-free environments for instance ONNX and use the above best practices to assess predictive consistency between scikitlearn and ONNX prediction functions on validation set
- Document good practices to detect temporal distribution drift for deployed model and good practices for retraining on fresh data without causing catastrophic predictive performance regressions

21 More didactic documentation

- More and more options have been added to scikitlearn As a result the documentation is crowded which makes it hard for beginners to get the big picture Some work could be done in prioritizing the information

1184 Subpackage-specific goals

sklearncluster

- kmeans variants for non-Euclidean distances if we can show these have benefits beyond hierarchical clustering

sklearnensemble

- a stacking implementation

sklearnmodelselection

- multimetric scoring is slow 9326
- perhaps we want to be able to get back more than multiple metrics
- the handling of random states in CV (Cross-Validation) splitters is a poor design and contradicts the validation of similar parameters in estimators

- exploit warmstarting and path algorithms so the benefits of EstimatorCV objects can be accessed via

GridSearchCV and used in Pipelines 1626

- Crossvalidation should be able to be replaced by OOB estimates whenever a crossvalidation iterator is used
- Redundant computations in pipelines should be avoided related to point above cf daskml

sklearnneighbors

- Ability to substitute a custom approximate precomputed nearest neighbors implementation for ours in almost all contexts that nearest neighbors are used for learning 10463

sklearnpipeline

- Performance issues with Pipelinememory
- see “Everything in Scikitlearn should conform to our API (Application Programming Interface) contract” above

119 Scikitlearn governance and decisionmaking

The purpose of this document is to formalize the governance process used by the scikitlearn project to clarify how decisions are made and how the various elements of our community interact This document establishes a decision making structure that takes into account feedback from all members of the community and strives to find consensus while avoiding any deadlocks

148 Chapter 1 Welcome to scikitlearn

scikitlearn user guide Release 0213

This is a meritocratic consensusbased community project Anyone with an interest in the project can join the community contribute to the project design and participate in the decision making process This document describes how that participation takes place and how to set about earning merit within the project community

1191 Roles And Responsibilities

Contributors

Contributors are community members who contribute in concrete ways to the project Anyone can become a contributor and contributions can take many forms – not only code – as detailed in the contributors guide

Core developers

Core developers are community members who have shown that they are dedicated to the continued development of the project through ongoing engagement with the community They have shown they can be trusted to maintain Scikit learn with care Being a core developer allows contributors to more easily carry on with their project related activities by giving them direct access to the project’s repository and is represented as being an organization member on the scikitlearn GitHub organization Core developers are expected to review code contributions can merge approved pull requests can cast votes for and against merging a pullrequest and can be involved in deciding major changes to the API (Application Programming Interface)

New core developers can be nominated by any existing core developers Once they have been nominated there will be a vote by the current core developers Voting on new core developers is one of the few activities that takes place on the project’s private management list While it is expected that most votes will be unanimous a twothirds majority of the cast votes is enough The vote needs to be open for at least 1 week

Core developers that have not contributed to the project commits or GitHub comments in the past 12 months will be asked if they want to become emeritus core developers and recant their commit and voting rights until they become active again The list of core developers active and emeritus with dates at which they became active is public on the scikitlearn website

Technical Committee

The Technical Committee TC members are core developers who have additional responsibilities to ensure the smooth running of the project TC members are expected to participate in strategic planning and approve changes to the governance model The purpose of the TC is to ensure a smooth progress from the bigpicture perspective Indeed changes that impact the full project require a synthetic analysis and a consensus that is both explicit and informed In cases that the core developer community which includes the TC members fails to reach such a consensus in the required time frame the TC is the entity to resolve the issue Membership of the TC is by nomination by a core developer A nomination will result in discussion which cannot take more than a month and then a vote by the core developers which will stay open for a week TC membership votes are subject to a twothird majority of all cast votes as well as a simple majority approval of all the current TC members TC members who do not actively engage with the TC duties are expected to resign

The initial Technical Committee of scikitlearn consists of Alexandre Gramfort Olivier Grisel Andreas Müller Joel Nothman Hanmin Qin Gaël Varoquaux and Roman Yurchak

1192 Decision Making Process

Decisions about the future of the project are made through discussion with all members of the community All non sensitive project management discussion takes place on the project contributors’ mailing list and the issue tracker Occasionally sensitive discussion occurs on a private list

119 Scikitlearn governance and decisionmaking 149

scikitlearn user guide Release 0213

Scikitlearn uses a “consensus seeking” process for making decisions The group tries to find a resolution that has no open objections among core developers At any point during the discussion any coredeveloper can call for a vote which will conclude one month from the call for the vote Any vote must be backed by a SLEP If no option can gather two thirds of the votes cast the decision is escalated to the TC which in turn will use consensus seeking with the fallback option of a simple majority vote if no consensus can be found within a month This is what we hereafter may refer to as “the decision making process”

Decisions in addition to adding core developers and TC membership as above are made according to the following rules

- Minor Documentation changes such as typo fixes or addition correction of a sentence but no change of the scikitlearnorg landing page or the “about” page Requires 1 by a core developer no 1 by a core developer lazy consensus happens on the issue or pull request page Core developers are expected to give “reasonable time” to others to give their opinion on the pull request if they’re not confident others would agree
- Code changes and major documentation changes require 1 by two core developers no 1 by a core developer lazy consensus happens on the issue of pullrequest page
- Changes to the API (Application Programming Interface) principles and changes to dependencies or supported versions happen via a Enhancement proposals SLEPs and follows the decisionmaking process outlined above
- Changes to the governance model use the same decision process outlined above

If a veto 1 vote is cast on a lazy consensus the proposer can appeal to the community and core developers and the change can be approved or rejected using the decision making procedure outlined above

1193 Enhancement proposals SLEPs

For all votes a proposal must have been made public and discussed before the vote Such proposal must be a consolidated document in the form of a ‘ScikitLearn Enhancement Proposal’ SLEP rather than a long discussion on an issue A SLEP must be submitted as a pullrequest to enhancement proposals using the SLEP template

CHAPTER
TWO
SCIKITLEARN TUTORIALS

21 An introduction to machine learning with scikitlearn

Section contents

In this section we introduce the machine learning vocabulary that we use throughout scikitlearn and give a simple learning example

211 Machine learning the problem setting

In general a learning problem considers a set of n samples of data and then tries to predict properties of unknown data. If each sample is more than a single number and for instance a multidimensional entry aka multivariate data it is said to have several attributes or features

Learning problems fall into a few categories

- supervised learning in which the data comes with additional attributes that we want to predict. Click here to go to the scikitlearn supervised learning page

This problem can be either -classification samples belong to two or more classes and we want to learn from already labeled data how to predict the class of unlabeled data. An example of a classification problem would be handwritten digit recognition in which the aim is to assign each input vector to one of a finite number of discrete categories

Another way to think of classification is as a discrete as opposed to continuous form of supervised learning where one has a limited number of categories and for each of the n samples provided one is to try to label them with the correct category or class

-regression if the desired output consists of one or more continuous variables then the task is called regression. An example of a regression problem would be the prediction of the length of a salmon as a function of its age and weight

- unsupervised learning in which the training data consists of a set of input vectors x without any corresponding target values. The goal in such problems may be to discover groups of similar examples within the data where it is called clustering or to determine the distribution of data within the input space known as density estimation or to project the data from a highdimensional space down to two or three dimensions for the purpose of visualization. Click here to go to the ScikitLearn unsupervised learning page

scikitlearn user guide Release 0213

Training set and testing set

Machine learning is about learning some properties of a data set and then testing those properties against another data set A common practice in machine learning is to evaluate an algorithm by splitting a data set into two We call one of those sets the training set on which we learn some properties we call the other set the testing set on which we test the learned properties

212 Loading an example dataset

scikitlearn comes with a few standard datasets for instance the iris and digits datasets for classification and the boston house prices dataset for regression

In the following we start a Python interpreter from our shell and then load the iris and digits datasets Our notational convention is that `!` denotes the shell prompt while `>` denotes the Python interpreter prompt

```
python
from sklearn import datasets
iris = datasets.load_iris()
digits = datasets.load_digits()
```

A dataset is a dictionarylike object that holds all the data and some metadata about the data This data is stored in the `data` member which is a `(n_samples, n_features)` array In the case of supervised problem one or more response variables are stored in the `target` member More details on the different datasets can be found in the dedicated section

For instance in the case of the digits dataset `digits.data` gives access to the features that can be used to classify the digits samples

```
print(digits.data)
0 0 5 0 0 0
0 0 0 10 0 0
0 0 0 16 9 0
```

```
0 0 1 6 0 0
0 0 2 12 0 0
0 0 10 12 1 0
```

`digits.target` gives the ground truth for the digit dataset that is the number corresponding to each digit image that we are trying to learn

```
digits.target
array(0 1 2 8 9 8)
```

Shape of the data arrays

The data is always a 2D array shape `(n_samples, n_features)` although the original data may have had a different shape In the case of the digits each original sample is an image of shape `(8, 8)` and can be accessed using

```
digits.images[0]
array([[0, 0, 5, 13, 9, 1, 0, 0],
       [0, 0, 13, 15, 10, 15, 5, 0],
       [0, 3, 15, 2, 0, 11, 8, 0],
       [0, 4, 12, 0, 0, 8, 8, 0],
       [0, 5, 8, 0, 0, 9, 8, 0],
       [0, 4, 11, 0, 1, 12, 7, 0],
       [0, 2, 14, 5, 10, 12, 0, 0],
       [0, 0, 6, 13, 10, 0, 0, 0]])
```

scikitlearn user guide Release 0213

This simple example on this dataset illustrates how starting from the original problem one can shape the data for consumption in scikitlearn

Loading from external datasets

To load from an external dataset please refer to loading external datasets

213 Learning and predicting

In the case of the digits dataset the task is to predict given an image which digit it represents We are given samples of each of the 10 possible classes the digits zero through nine on which we fit an estimator to be able to predict the classes to which unseen samples belong

In scikitlearn an estimator for classification is a Python object that implements the methods fit(X, y) and predict()

An example of an estimator is the class sklearn.svm.SVC which implements support vector classification The estimator's constructor takes as arguments the model's parameters

For now we will consider the estimator as a black box

```
from sklearn import svm
clf = svm.SVC(gamma=0.001, C=100)
```

Choosing the parameters of the model

In this example we set the value of gamma manually To find good values for these parameters we can use tools such as grid search and cross validation

The clf for classifier estimator instance is first fitted to the model that is it must learn from the model This is done by passing our training set to the fit method For the training set we'll use all the images from our dataset except for the last image which we'll reserve for our predicting We select the training set with the 1 Python syntax which produces a new array that contains all but the last item from digitsdata

```
clf.fit(digitsdata[:-1], digitstarget[:-1])
SVCC1000, cachesize=200, class_weight=None, coef0=0.0,
decision_function_shape='ovr', degree=3, gamma=0.001, kernel='rbf',
max_iter=1, probability=False, random_state=None, shrinking=True,
tol=0.0001, verbose=False
```

Now you can predict new values In this case you'll predict using the last image from digitsdata By predicting you'll determine the image from the training set that best matches the last image

```
clf.predict(digitsdata[-1])
array(8)
```

21 An introduction to machine learning with scikitlearn 153

scikitlearn user guide Release 0213

The corresponding image is

As you can see it is a challenging task after all the images are of poor resolution Do you agree with the classifier

A complete example of this classification problem is available as an example that you can run and study Recognizing handwritten digits

214 Model persistence

It is possible to save a model in scikitlearn by using Python’s builtin persistence model pickle

```
from sklearn import svm
from sklearn import datasets
clf = svmSVC(gamma=scale
iris = datasets.load_iris
X, y = iris.data, iris.target
clf.fit(X, y)
SVCC10, cache_size=200, class_weight=None, coef0=0.0
decision_function_shape='ovr', degree=3, gamma=scale, kernel='rbf'
max_iter=1, probability=False, random_state=None, shrinking=True
tol=0.0001, verbose=False
import pickle
s = pickle.dumps(clf)
clf2 = pickle.loads(s)
clf2.predict(X01)
array(0)
y0
0
```

In the specific case of scikitlearn it may be more interesting to use joblib’s replacement for pickle joblib.dump joblib.load which is more efficient on big data but it can only pickle to the disk and not to a string

```
from joblib import dump, load
dump(clf, filename='joblib')
```

Later you can reload the pickled model possibly in another Python process with

```
clf = load(filename='joblib')
```

Note joblib.dump and joblib.load functions also accept filelike object instead of filenames More information on data persistence with Joblib is available here

Note that pickle has some security and maintainability issues Please refer to section Model persistence for more detailed information about model persistence with scikitlearn

scikitlearn user guide Release 0213

215 Conventions

scikitlearn estimators follow certain rules to make their behavior more predictive These are described in more detail in the Glossary of Common Terms and API (Application Programming Interface) Elements

Type casting

Unless otherwise specified input will be cast to float64

```
import numpy as np
from sklearn import randomprojection
rng = np.random.RandomState(0)
X = rng.rand(10, 2000)
X = np.array(X, dtype=float32)
X.dtype
dtypefloat32
transformer = randomprojection.GaussianRandomProjection()
X_new = transformer.fit_transform(X)
X_new.dtype
dtypefloat64
```

In this example X is float32 which is cast to float64 by fit_transform(X)

Regression targets are cast to float64 and classification targets are maintained

```
from sklearn import datasets
from sklearn.svm import SVC (Support Vector Classification)
iris = datasets.load_iris()
clf = SVC(gamma=scale)
clf.fit(iris.data, iris.target)
SVCC10 cachesize=200 classweight=None coef=0.00
decisionfunctionshape=ovr degree=3 gamma=scale kernel=rbf
max_iter=1 probability=False randomstate=None shrinking=True
tol=0.001 verbose=False
list(clf.predict(iris.data))
[0, 0, 0]
clf.fit(iris.data, iris.target_names[iris.target])
SVCC10 cachesize=200 classweight=None coef=0.00
decisionfunctionshape=ovr degree=3 gamma=scale kernel=rbf
max_iter=1 probability=False randomstate=None shrinking=True
tol=0.001 verbose=False
list(clf.predict(iris.data))
setosa setosa setosa
```

Here the first predict returns an integer array since iris.target an integer array was used in fit The second predict returns a string array since iris.target_names was for fitting

Refitting and updating parameters

Hyperparameters of an estimator can be updated after it has been constructed via the set_params method Calling fit more than once will overwrite what was learned by any previous fit

scikitlearn user guide Release 0213

```
import numpy as np
from sklearn.datasets import loadiris
from sklearn.svm import SVC (Support Vector Classification)
X, y = loadiris(returnXy=True)
clf = SVC (Support Vector Classification)
clf.set_params(kernel='linear', fit_X_y=
SVCC10, cache_size=200, class_weight=None, coef=0.00
decision_function_shape='ovr', degree=3, gamma='auto', deprecated
kernel='linear', max_iter=1, probability=False, random_state=None
shrinking=True, tol=0.0001, verbose=False)
clf.predict(X5)
array([0, 0, 0, 0, 0])
clf.set_params(kernel='rbf', gamma='scale', fit_X_y=
SVCC10, cache_size=200, class_weight=None, coef=0.00
decision_function_shape='ovr', degree=3, gamma='scale', kernel='rbf'
max_iter=1, probability=False, random_state=None, shrinking=True
tol=0.0001, verbose=False)
clf.predict(X5)
array([0, 0, 0, 0, 0])
```

Here the default kernel 'rbf' is first changed to 'linear' via `SVC.set_params` after the estimator has been constructed and changed back to 'rbf' to refit the estimator and to make a second prediction.

Multiclass vs multilabel fitting

When using multiclass classifiers, the learning and prediction task that is performed is dependent on the format of the target data fit upon.

```
from sklearn.svm import SVC (Support Vector Classification)
from sklearn.multiclass import OneVsRestClassifier
from sklearn.preprocessing import LabelBinarizer
X = [1, 2, 2, 4, 4, 5, 3, 2, 3, 1]
y = [0, 0, 1, 1, 2]
classifier = OneVsRestClassifier(estimator=SVC(gamma='scale',
random_state=0))
classifier.fit(X, y)
classifier.predict(X)
array([0, 0, 1, 1, 2])
```

In the above case, the classifier is fit on a 1d array of multiclass labels and the `predict` method therefore provides corresponding multiclass predictions. It is also possible to fit upon a 2d array of binary label indicators.

```
y = LabelBinarizer().fit_transform(y)
classifier.fit(X, y)
classifier.predict(X)
array([[1, 0, 0],
       [0, 1, 0],
       [0, 0, 0],
       [0, 0, 0]])
```

Here the classifier is fit on a 2d binary label representation of `y` using the `LabelBinarizer`. In this case, `predict` returns a 2d array representing the corresponding multilabel predictions.

scikitlearn user guide Release 0213

Note that the fourth and fifth instances returned all zeroes indicating that they matched none of the three labels fit upon With multilabel outputs it is similarly possible for an instance to be assigned multiple labels

```
from sklearn.preprocessing import MultiLabelBinarizer
```

```
y = [0, 1, 0, 2, 1, 3, 0, 2, 3, 2, 4]
```

```
mlb = MultiLabelBinarizer(fit_transformer)
```

```
mlb.fit(X, y)
```

```
array([[1, 0, 0, 0]
```

```
       [0, 1, 0, 0]
```

scikitlearn user guide Release 0213

When the data is not initially in the nsamples nfeatures shape it needs to be preprocessed in order to be used by scikitlearn

An example of reshaping data would be the digits dataset

The digits dataset is made of 1797 8x8 images of handwritten digits

digits datasetsloadaddigits

digitsimagesshape

1797 8 8

import matplotlib.pyplot as plt

plt.imshow(digitsimages[1], cmap=plt.cm.gray)

matplotlib.image.AxesImage object at

To use this dataset with scikitlearn we transform each 8x8 image into a feature vector of length 64

data = digitsimages.reshape(digitsimages.shape[0], 1)

Estimators objects

Fitting data the main API (Application Programming Interface) implemented by scikitlearn is that of the estimator An estimator is any object that

from data it may be a classification regression or clustering algorithm or a transformer that extracts filters useful

features from raw data

All estimator objects expose a fit method that takes a dataset usually a 2d array

estimator.fit(data)

Estimator parameters All the parameters of an estimator can be set when it is instantiated or by modifying the

corresponding attribute

estimator.estimator_param1 param22

estimator.param1

1

Estimated parameters When data is fitted with an estimator parameters are estimated from the data at hand All the

estimated parameters are attributes of the estimator object ending by an underscore

estimator.estimated_param

scikitlearn user guide Release 0213

222 Supervised learning predicting an output variable from highdimensional observations

The problem solved in supervised learning

Supervised learning consists in learning the link between two datasets the observed data X and an external variable y that we are trying to predict usually called “target” or “labels” Most often y is a 1D array of length n_{samples}

All supervised estimators in scikitlearn implement a `fit(X, y)` method to fit the model and a `predict(X)` method that given unlabeled observations X returns the predicted labels y

Vocabulary classification and regression

If the prediction task is to classify the observations in a set of finite labels in other words to “name” the objects observed the task is said to be a classification task On the other hand if the goal is to predict a continuous target variable it is said to be a regression task

When doing classification in scikitlearn y is a vector of integers or strings

Note See the Introduction to machine learning with scikitlearn Tutorial for a quick runthrough on the basic machine learning vocabulary used within scikitlearn

Nearest neighbor and the curse of dimensionality

Classifying irises

22 A tutorial on statistical learning for scientific data processing 159

scikitlearn user guide Release 0213

The iris dataset is a classification task consisting in identifying 3 different types of irises Setosa Versicolour and Virginica from their petal and sepal length and width

```
import numpy as np
from sklearn import datasets
iris = datasets.load_iris()
iris_X = iris.data
iris_y = iris.target
np.unique(iris_y)
array([0, 1, 2])
```

kNearest neighbors classifier

The simplest possible classifier is the nearest neighbor given a new observation X_{test} find in the training set ie the data used to train the estimator the observation with the closest feature vector Please see the Nearest Neighbors section of the online Scikitlearn documentation for more information about this type of classifier

Training set and testing set

While experimenting with any learning algorithm it is important not to test the prediction of an estimator on the data used to fit the estimator as this would not be evaluating the performance of the estimator on new data This is why datasets are often split into train and test data

scikitlearn user guide Release 0213

KNN k nearest neighbors classification example

Split iris data in train and test data

A random permutation to split the data randomly

`np.random.seed(0)`

`indices = np.random.permutation(len(irisX))`

`irisXtrain = irisX[indices[:10]]`

`irisYtrain = irisY[indices[:10]]`

`irisXtest = irisX[indices[10:]]`

`irisYtest = irisY[indices[10:]]`

Create and fit a nearest neighbor classifier

`from sklearn.neighbors import KNeighborsClassifier`

`knn = KNeighborsClassifier`

`knn.fit(irisXtrain, irisYtrain)`

`KNeighborsClassifier(algorithm='auto', leaf_size=30, metric='minkowski',`

`metric_params=None, n_jobs=None, n_neighbors=5, p=2,`

`weights='uniform')`

`knn.predict(irisXtest)`

`array([1, 2, 1, 0, 0, 0, 2, 1, 2, 0])`

`irisYtest`

`array([1, 1, 1, 0, 0, 0, 2, 1, 2, 0])`

The curse of dimensionality

For an estimator to be effective you need the distance between neighboring points to be less than some value ϵ which depends on the problem. In one dimension this requires on average $\sim 1/\epsilon$ points. In the context of the above ϵ -NN example if the data is described by just one feature with values ranging from 0 to 1 and with n training observations then new data will be no further away than $1/n$. Therefore the nearest neighbor decision rule will be efficient as soon as $1/n$ is small compared to the scale of between-class feature variations.

If the number of features is d you now require $\sim 1/\epsilon^d$ points. Let's say that we require 10 points in one dimension now 10^d points are required in d dimensions to pave the 0-1 space. As d becomes large the number of training points required for a good estimator grows exponentially.

For example if each point is just a single number 8 bytes then an effective ϵ -NN estimator in a paltry ~ 20 dimensions would require more training data than the current estimated size of the entire internet ~ 1000 Exabytes or 22 A tutorial on statistical learning for scientific data processing 161

scikitlearn user guide Release 0213

so

This is called the curse of dimensionality and is a core problem that machine learning addresses

Linear model from regression to sparsity

Diabetes dataset

The diabetes dataset consists of 10 physiological variables age sex weight blood pressure measure on 442 patients and an indication of disease progression after one year

diabetes datasetsloaddiabetes

diabetesXtrain diabetesdata20

diabetesXtest diabetesdata20

diabetesytrain diabetestarget20

diabetesytest diabetestarget20

The task at hand is to predict disease progression from physiological variables

Linear regression

LinearRegression in its simplest form fits a linear model to the data set by adjusting a set of parameters in order to make the sum of the squared residuals of the model as small as possible

Linear models

- data
- target variable
- Coefficients
- Observation noise

05855512036503 05830717085554 057058999437

Note Capturing in the fitted parameters noise that prevents the model to generalize to new data is called overfitting

The bias introduced by the ridge regression is called a regularization

Sparsity
Fitting only features 1 and 2

scikitlearn user guide Release 0213

Note A representation of the full diabetes dataset would involve 11 dimensions 10 feature dimensions and one of the target variable It is hard to develop an intuition on such representation but it may be useful to keep in mind that it would be a fairly empty space

We can see that although feature 2 has a strong coefficient on the full model it conveys little information on ywhen considered with feature 1

To improve the conditioning of the problem ie mitigating the The curse of dimensionality it would be interesting to select only the informative features and set noninformative ones like feature 2 to 0 Ridge regression will decrease their contribution but not set them to zero Another penalization approach called Lasso least absolute shrinkage and selection operator can set some coefficients to zero Such methods are called sparse method and sparsity can be seen as an application of Occam’s razor prefer simpler models

```
regr = linearmodelLasso
scores = regr.set_params(alpha=alpha)
fit_diabetes_X_train, diabetes_y_train =
score_diabetes_X_test, diabetes_y_test =

scikitlearn user guide Release 0213

Different algorithms for the same problem

Different algorithms can be used to solve the same mathematical problem For instance the Lasso object in scikit learn solves the lasso regression problem using a coordinate descent method that is efficient on large datasets However scikitlearn also provides the LassoLars object using the LARS algorithm which is very efficient for problems in which the weight vector estimated is very sparse ie problems with very few observations

Classification

For classification as in the labeling iris task linear regression is not the right approach as it will give too much weight to data far from the decision frontier A linear approach is to fit a sigmoid function or logistic function

$\sigma(\text{offset}) = \frac{1}{1 + \exp(-\text{offset})}$

$\log \text{linear model}$

`LogisticRegression(solver='lbfgs', C=1e5)`

`multiclassmultinomial`

`LogisticRegression`

`LogisticRegression(C=1000000, class_weight=None, dual=False,`

`fit_intercept=True, intercept_scaling=1, l1_ratio=None, max_iter=100,`

`multiclassmultinomial, n_jobs=None, penalty='l2', random_state=None,`

`solver='lbfgs', tol=0.0001, verbose=0, warm_start=False)`

This is known as LogisticRegression

166 Chapter 2 scikitlearn Tutorials

scikitlearn user guide Release 0213

Multiclass classification

If you have several classes to predict an option often used is to fit oneversusall classifiers and then use a voting heuristic for the final decision

Shrinkage and sparsity with logistic regression

TheCparameter controls the amount of regularization in the LogisticRegression object a large value

forCresults in less regularization penaltyl2 gives Shrinkage ie nonsparse coefficients while

penaltyl1 gives Sparsity

Support vector machines SVMs

Linear SVMs

Support Vector Machines belong to the discriminant model family they try to find a combination of samples to build

a plane maximizing the margin between the two classes Regularization is set by the Cparameter a small value for C

means the margin is calculated using many or all of the observations around the separating line more regularization

a large value for Cmeans the margin is calculated on observations close to the separating line less regularization

Unregularized SVM (Support Vector Machine) Regularized SVM (Support Vector Machine) default

22 A tutorial on statisticallearning for scientific data processing 167

scikitlearn user guide Release 0213

Example

•Plot different SVM (Support Vector Machine) classifiers in the iris dataset

SVMs can be used in regression – SVR (Support Vector Regression) Support Vector Regression– or in classification – SVC (Support Vector Classification)

from sklearn import svm

svc = svm.SVC(kernel='linear')

svc.fit(X_train, y_train)

SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,

decision_function_shape='ovr', degree=3, gamma='auto_deprecated',

kernel='linear', max_iter=1, probability=False, random_state=None,

shrinking=True, tol=0.001, verbose=False)

Warning: Normalizing data

For many estimators including the SVMs having datasets with unit standard deviation for each feature is important

to get good prediction

Using kernels

Classes are not always linearly separable in feature space. The solution is to build a decision function that is not linear

but may be polynomial instead. This is done using the kernel trick that can be seen as creating a decision energy by

positioning kernels on observations

Linear kernel Polynomial kernel

svc = svm.SVC(kernel='linear') svc = svm.SVC(kernel='poly',

degree=3,

degree polynomial degree)

170 Chapter 2 scikitlearn Tutorials

scikitlearn user guide Release 0213

Crossvalidation generators

Scikitlearn has a collection of classes which can be used to generate lists of traintest indices for popular cross validation strategies

They expose a split method which accepts the input dataset to be split and yields the traintest set indices for each iteration of the chosen crossvalidation strategy

This example shows an example usage of the split method

```
from sklearn.model_selection import KFold crossvalscore
```

```
X = a a a b b c c c c c
```

```
kfold = KFold(n_splits=5)
```

```
for train_indices, test_indices in kfold.split(X):
```

```
    print('Train: %s, Test: %s' % (train_indices, test_indices))
```

```
Train: [2 3 4 5 6 7 8 9] Test: [0 1]
```

```
Train: [0 1 4 5 6 7 8 9] Test: [2 3]
```

```
Train: [0 1 2 3 6 7 8 9] Test: [4 5]
```

```
Train: [0 1 2 3 4 5 8 9] Test: [6 7]
```

```
Train: [0 1 2 3 4 5 6 7] Test: [8 9]
```

The crossvalidation can then be performed easily

```
svc.fit(X_train, y_train).score(X_test, y_test)
```

```
for train, test in kfold.split(X_digits):
```

```
    0.963 0.922 0.963 0.963 0.930
```

The crossvalidation score can be directly calculated using the crossvalscore helper Given an estimator the crossvalidation object and the input dataset the crossvalscore splits the data repeatedly into a training and a testing set trains the estimator using the training set and computes the scores based on the testing set for each iteration of crossvalidation

By default the estimator's score method is used to compute the individual scores

Refer the metrics module to learn more on the available scoring methods

```
cross_val_score(svc, X_digits, y_digits, cv=kfold, n_jobs=1)
```

```
array([0.96388889, 0.92222222, 0.9637883, 0.9637883, 0.93036212])
```

n_jobs=1 means that the computation will be dispatched on all the CPUs of the computer

Alternatively the scoring argument can be provided to specify an alternative scoring method

```
cross_val_score(svc, X_digits, y_digits, cv=kfold,
```

```
                scoring=precision_macro)
```

```
array([0.96578289, 0.92708922, 0.96681476, 0.96362897, 0.93192644])
```

Exercise

On the
digits dataset plot the crossvalidation score of a SVC (Support Vector Classification) estimator with an linear kernel as a function of parameter C
use a logarithmic grid of points from 1 to 10

```
import numpy as np
from sklearn.model_selection import cross_val_score
from sklearn import datasets, svm
digits = datasets.load_digits()
X, y = digits.data, digits.target
svc = svm.SVC(kernel='linear')
Cs = np.logspace(0, 10, 10)
172 Chapter 2 scikitlearn Tutorials
```

Solution Crossvalidation on Digits Dataset Exercise

Gridsearch and crossvalidated estimators

Gridsearch

scikitlearn provides an object that given data computes the score during the fit of an estimator on a parameter grid and chooses the parameters to maximize the crossvalidation score This object takes an estimator during the construction and exposes an estimator API (Application Programming Interface)

from sklearnmodelselection import GridSearchCV crossvalscore

Cs nplogspace6 1 10

clf GridSearchCVestimatorsvc paramgriddictCCs

njobs1

clffitXdigits1000 ydigits1000

GridSearchCVcvNone

0925

clfbestestimatorC

00077

Prediction performance on test set is not as good as on train set

clfscoreXdigits1000 ydigits1000

0943

By default the GridSearchCV uses a 3fold crossvalidation However if it detects that a classifier is passed rather than a regressor it uses a stratified 3fold The default will change to a 5fold crossvalidation in version 022

Nested crossvalidation

crossvalscoreclf Xdigits ydigits

array0938 0963 0944

Two crossvalidation loops are performed in parallel one by the GridSearchCV estimator to set gamma and the other one by crossvalscore to measure the prediction performance of the estimator The resulting scores are unbiased estimates of the prediction score on new data

Warning You cannot nest objects with parallel computing njobs different than 1

Crossvalidated estimators

Crossvalidation to set a parameter can be done more efficiently on an algorithmbyalgorithm basis This is why for certain estimators scikitlearn exposes Crossvalidation evaluating estimator performance estimators that set their parameter automatically by crossvalidation

224 Unsupervised learning seeking representations of the data

Clustering grouping observations together

The problem solved in clustering

Given the iris dataset if we knew that there were 3 types of iris but did not have access to a taxonomist to label

them we could try a clustering task split the observations into wellseparated group called clusters

174 Chapter 2 scikitlearn Tutorials

scikitlearn user guide Release 0213

Kmeans clustering

Note that there exist a lot of different clustering criteria and associated algorithms The simplest clustering algorithm is Kmeans

from sklearn import cluster datasets

iris datasetsloadiris

Xiris irisdata

yiris iristarget

kmeans clusterKMeansnclusters3

kmeansfitXiris

KMeansalgorithmauto copyxTrue initkmeans

printkmeanslabels10

1 1 1 1 1 0 0 0 0 2 2 2 2 2

printyiris10

0 0 0 0 0 1 1 1 1 2 2 2 2 2

Warning There is absolutely no guarantee of recovering a ground truth First choosing the right number of clusters is hard Second the algorithm is sensitive to initialization and can fall into local minima although scikit

learn employs several tricks to mitigate this issue

Bad initialization 8 clusters Ground truth

Don't overinterpret clustering results

Application example vector quantization

Clustering in general and KMeans in particular can be seen as a way of choosing a small number of exemplars to compress the information The problem is sometimes known as vector quantization For instance this can be used

Raw image Kmeans quantization Equal bins Image histogram

Hierarchical agglomerative clustering Ward

A Hierarchical clustering method is a type of cluster analysis that aims to build a hierarchy of clusters. In general, the

various approaches of this technique are either

- Agglomerative (bottomup) approaches: each observation starts in its own cluster, and clusters are iteratively merged in such a way to minimize a linkage criterion. This approach is particularly interesting when the clusters of interest are made of only a few observations. When the number of clusters is large, it is much more computationally efficient than kmeans.

- Divisive (topdown) approaches: all observations start in one cluster, which is iteratively split as one moves down the hierarchy. For estimating large numbers of clusters, this approach is both slow (due to all observations starting as one cluster) and statistically illposed.

Connectivity-constrained clustering

With agglomerative clustering, it is possible to specify which samples can be clustered together by giving a connectivity graph. Graphs in scikitlearn are represented by their adjacency matrix. Often, a sparse matrix is used. This

can be useful for instance to retrieve connected regions, sometimes also referred to as connected components. When

176 Chapter 2 scikitlearn Tutorials

```
scikitlearn user guide Release 0.21.3
clustering an image
from scipy.ndimage.filters import gaussian_filter
import matplotlib.pyplot as plt
import skimage
from skimage.data import coins
from skimage.transform import rescale
from sklearn.feature_extraction.image import grid_to_graph
from sklearn.cluster import AgglomerativeClustering
# these were introduced in skimage 0.14
if LooseVersion(skimage.__version__) < LooseVersion('0.14'):
    rescale_params = {'antialiasing': False, 'multichannel': False}
else:
    rescale_params = {}
```

```
# Generate data
orig_coins = coins
# Resize it to 20% of the original size to speed up the processing
# Applying a Gaussian filter for smoothing prior to downscaling
# reduces aliasing artifacts
smoothed_coins = gaussian_filter(orig_coins, sigma=2)
```

Feature agglomeration

We have seen that sparsity could be used to mitigate the curse of dimensionality i.e. an insufficient amount of observations compared to the number of features. Another approach is to merge together similar features: feature agglomeration. This approach can be implemented by clustering in the feature direction, in other words clustering.

transform andinversettransform methods

Some estimators expose a transform method for instance to reduce the dimensionality of the dataset

Decompositions from a signal to components and loadings

Components and loadings

If X is our multivariate data then the problem that we are trying to solve is to rewrite it on a different observational basis we want to learn loadings L and a set of components C such that $X = L C$ Different criteria exist to choose the components

Principal component analysis PCA (Principal Component Analysis)

Principal component analysis PCA (Principal Component Analysis) selects the successive components that explain the maximum variance in the signal

178 Chapter 2 scikitlearn Tutorials

scikitlearn user guide Release 0213

The point cloud spanned by the observations above is very flat in one direction one of the three univariate features can almost be exactly computed using the other two PCA (Principal Component Analysis) finds the directions in which the data is not flat When used to transform data PCA (Principal Component Analysis) can reduce the dimensionality of the data by projecting on a principal subspace

```
Create a signal with only 2 useful dimensions
x1 = np.random.randn(100)
x2 = np.random.randn(100)
x3 = x1 * x2
X = np.column_stack((x1, x2, x3))

from sklearn import decomposition
pca = decomposition.PCA()
pca.fit(X)

23 Working With Text Data

The goal of this guide is to explore some of the main scikitlearn tools on a single practical task analyzing a collection of text documents newsgroups posts on twenty different topics

In this section we will see how to

- load the file contents and the categories
- extract feature vectors suitable for machine learning
- train a linear model to perform categorization
- use a grid search strategy to find a good configuration of both the feature extraction components and the classifier

231 Tutorial setup

To get started with this tutorial you must first install scikitlearn and all of its required dependencies

Please refer to the installation instructions page for more information and for systemspecific instructions

The source of this tutorial can be found within your scikitlearn folder

`scikitlearndoctutorialtextanalytics`

The source can also be found on Github

The tutorial folder should contain the following subfolders

- `rst` files the source of the tutorial document written with sphinx
- `data` folder to put the datasets used during the tutorial
- `skeletons` sample incomplete scripts for the exercises
- `solutions` solutions of the exercises

You can already copy the skeletons into a new folder somewhere on your harddrive named

`sklearnututworkspace` where you will edit your own files for the exercises while keeping the original skeletons intact

`cp r skeletons workdirectorysklearnututworkspace`

186 Chapter 2 scikitlearn Tutorials

scikitlearn user guide Release 0213

Machine learning algorithms need data Go to each TUTORIALHOMEdata subfolder and run the fetchdatapy script from there after having read them first

For instance

```
cd TUTORIALHOMEdatalanguages
less fetchdatapy
python fetchdatapy
```

232 Loading the 20 newsgroups dataset

The dataset is called “Twenty Newsgroups” Here is the official description quoted from the website

The 20 Newsgroups data set is a collection of approximately 20000 newsgroup documents partitioned nearly evenly across 20 different newsgroups To the best of our knowledge it was originally collected by Ken Lang probably for his paper “Newsweeder Learning to filter netnews” though he does not explicitly mention this collection The 20 newsgroups collection has become a popular data set for experiments in text applications of machine learning techniques such as text classification and text clustering

In the following we will use the builtin dataset loader for 20 newsgroups from scikitlearn Alternatively it is possible to download the dataset manually from the website and use the sklearndatasetsloadfiles function by pointing it to the 20newsbydatetrain subfolder of the uncompressed archive folder

In order to get faster execution times for this first example we will work on a partial dataset with only 4 categories out of the 20 available in the dataset

```
categories altatheism socreligionchristian
compgraphics scimed
```

We can now load the list of files matching those categories as follows

```
from sklearndatasets import fetch20newsgroups
twentytrain fetch20newsgroupssubsettrain
categoriescategories shuffle True randomstate42
```

The returned dataset is a scikitlearn “bunch” a simple holder object with fields that can be both accessed as pythondict keys or object attributes for convenience for instance the targetnames holds the list of the requested category names

```
twentytraintargetnames
altatheism compgraphics scimed socreligionchristian
```

The files themselves are loaded in memory in the data attribute For reference the filenames are also available

```
twentytraindata
twentytrainfilenames
```

Let’s print the first lines of the first loaded file

```
printjointtwentytraindata0split n3

Subject Converting images to HP LaserJet III
NntpPostingHost hampton
printtwentytraintargetnamesttwentytraintarget0
compgraphics
```

scikitlearn user guide Release 0213

Supervised learning algorithms will require a category label for each document in the training set In this case the category is the name of the newsgroup which also happens to be the name of the folder holding the individual documents For speed and space efficiency reasons scikitlearn loads the target attribute as an array of integers that corresponds to the index of the category name in the targetnames list The category integer id of each sample is stored in the target attribute

twentytraintarget10

scimed

scimed

scimed

You might have noticed that the samples were shuffled randomly when we called fetch20newsgroups

shuffleTrue randomstate42 this is useful if you wish to select only a subset of samples to quickly

train a model and get a first idea of the results before retraining on the complete dataset later

233 Extracting features from text files

In order to perform machine learning on text documents we first need to turn the text content into numerical feature vectors

Bags of words

The most intuitive way to do so is to use a bags of words representation

1 Assign a fixed integer id to each word occurring in any document of the training set for instance by building a dictionary from words to integer indices

2 For each document i count the number of occurrences of each word wand store it in X_{ij} as the value

of featurejwherejis the index of word win the dictionary

The bags of words representation implies that nfeatures is the number of distinct words in the corpus this number is typically larger than 100000

Ifnsamples 10000 storingXas a NumPy array of type float32 would require 10000 x 100000 x 4 bytes

4GB in RAM which is barely manageable on today's computers

Fortunately most values in X will be zeros since for a given document less than a few thousand distinct words will be used For this reason we say that bags of words are typically highdimensional sparse datasets We can save a lot of memory by only storing the nonzero parts of the feature vectors in memory

scikitlearn user guide Release 0213

scipy sparse matrices are data structures that do exactly this and scikitlearn has builtin support for these structures

Tokenizing text with scikitlearn

Text preprocessing tokenizing and filtering of stopwords are all included in CountVectorizer which builds a dictionary of features and transforms documents to feature vectors

```
from sklearn.feature_extraction.text import CountVectorizer
```

```
countvect = CountVectorizer
```

```
X_train_counts = countvect.fit_transform(train_data)
```

```
X_train_counts.shape
```

```
(2257, 35788)
```

CountVectorizer supports counts of Ngrams of words or consecutive characters. Once fitted the vectorizer has built a dictionary of feature indices

```
countvect.vocabulary.get_algorithm
```

```
4690
```

The index value of a word in the vocabulary is linked to its frequency in the whole training corpus

From occurrences to frequencies

Occurrence count is a good start but there is an issue: longer documents will have higher average count values than shorter documents even though they might talk about the same topics

To avoid these potential discrepancies it suffices to divide the number of occurrences of each word in a document by the total number of words in the document. These new features are called tf for Term Frequencies

Another refinement on top of tf is to downscale weights for words that occur in many documents in the corpus and are therefore less informative than those that occur only in a smaller portion of the corpus

This downscaling is called tf-idf for "Term Frequency times Inverse Document Frequency"

Both tf and tf-idf can be computed as follows using TfidfTransformer

```
from sklearn.feature_extraction.text import TfidfTransformer
```

```
tf_transformer = TfidfTransformer(use_idf=False).fit(X_train_counts)
```

```
X_train_tf = tf_transformer.transform(X_train_counts)
```

```
X_train_tf.shape
```

```
(2257, 35788)
```

In the above example code we firstly use the fit method to fit our estimator to the data and secondly the

transform method to transform our count matrix to a tfidf representation. These two steps can be com

bined to achieve the same end result faster by skipping redundant processing. This is done through using the

fit_transform method as shown below and as mentioned in the note in the previous section

```
tfidf_transformer = TfidfTransformer
```

```
X_train_tfidf = tfidf_transformer.fit_transform(X_train_counts)
```

```
X_train_tfidf.shape
```

```
(2257, 35788)
```

23 Working With Text Data 189

scikitlearn user guide Release 0213

234 Training a classifier

Now that we have our features we can train a classifier to try to predict the category of a post Let’s start with a naïve Bayes classifier which provides a nice baseline for this task scikitlearn includes several variants of this classifier the one most suitable for word counts is the multinomial variant

```
from sklearnnaivebayes import MultinomialNB
clf = MultinomialNBfitXtraintfidf twentytraintarget
```

To try to predict the outcome on a new document we need to extract the features using almost the same feature extract ing chain as before The difference is that we call transform instead offittransform on the transformers

since they have already been fit to the training set

scikitlearn user guide Release 0213

We achieved 835 accuracy Let’s see if we can do better with a linear support vector machine SVM (Support Vector Machine) which is widely regarded as one of the best text classification algorithms although it’s also a bit slower than naïve Bayes We can change the learner by simply plugging a different classifier object into our pipeline

```
from sklearn.linear_model import SGDClassifier
textclf = Pipeline(
    vect=CountVectorizer(),
    tfidf=TfidfTransformer(),
    clf=SGDClassifier(loss='hinge', penalty='l2',
        alpha=1e-3, random_state=42,
        max_iter=5, tol=None)
```

```
textclf.fit(train_data, train_target)
predicted = textclf.predict(doc_test)
np.mean(predicted == test_target)
0.9101
```

We achieved 913 accuracy using the SVM (Support Vector Machine) scikitlearn provides further utilities for more detailed performance analysis of the results

```
from sklearn import metrics
print(metrics.classification_report(test_target, predicted,
    target_names=test_target_names))
```

```
precision recall f1-score support
altatheism 0.95 0.80 0.87 319
compgraphics 0.87 0.98 0.92 389
scimed 0.94 0.89 0.91 396
socreligionchristian 0.90 0.95 0.93 398
accuracy 0.91 1.00 0.95 1502
macro avg 0.91 0.91 0.91 1502
weighted avg 0.91 0.91 0.91 1502
metrics.confusion_matrix(test_target, predicted)
array([[256, 11, 16, 36],
       [ 4, 380, 3, 2],
       [ 5, 35, 353, 3],
       [ 5, 11, 4, 378])
```

As expected the confusion matrix shows that posts from the newsgroups on atheism and Christianity are more often confused for one another than with computer graphics

237 Parameter tuning using grid search

We’ve already encountered some parameters such as use_idf in the TfidfTransformer. Classifiers tend to have many parameters as well eg MultinomialNB includes a smoothing parameter alpha and SGDClassifier has a penalty parameter alpha and configurable loss and penalty terms in the objective function see the module documentation or use the Python help function to get a description of these

Instead of tweaking the parameters of the various components of the chain it is possible to run an exhaustive search of the best parameters on a grid of possible values We try out all classifiers on either words or bigrams with or without idf and with a penalty parameter of either 0.01 or 0.001 for the linear SVM (Support Vector Machine)

```
scikitlearn user guide Release 0213
from sklearnmodelselection import GridSearchCV
parameters
vectngramrange 1 1 1 2
tfidfuseidf TrueFalse
clfalpha 1e2 1e3
```

Obviously such an exhaustive search can be expensive If we have multiple CPU cores at our disposal we can tell the grid searcher to try these eight parameter combinations in parallel with the njobs parameter If we give this parameter a value of 1 grid search will detect how many cores are installed and use them all

```
gsclf GridSearchCVtextclf parameters cv5 iid False njobs1
The grid search instance behaves like a normal scikitlearn model Let’s perform the search on a smaller subset
of the training data to speed up the computation

for paramname insortedparameterskeys
printsr paramname gsclfbestparamsparamname
```

```
clfalpha 0001
tfidfuseidf True
vectngramrange 1 1
```

A more detailed summary of the search is available at gsclfcvresults
Thecvresults parameter can be easily imported into pandas as a DataFrame for further inspection
Exercises

```
To do the exercises copy the content of the ‘skeletons’ folder as a new folder named ‘workspace’
cp r skeletons workspace
You can then edit the content of the workspace without fear of losing the original exercise instructions
Then fire an ipython shell and run the workinprogress script with
1 run workspaceexerciseXXscriptpy arg1 arg2 arg3
If an exception is triggered use debug to fireup a post mortem ipdb session
Refine the implementation and iterate until the exercise is solved
For each exercise the skeleton file provides all the necessary import statements boilerplate code to load the
data and sample code to evaluate the predictive accuracy of the model
```

scikitlearn user guide Release 0213

238 Exercise 1 Language identification

- Write a text classification pipeline using a custom preprocessor and CharNGramAnalyzer using data from Wikipedia articles as training set
- Evaluate the performance on some held out test set

ipython command line

```
run workspaceexercise01languagegetrainmodelpy datalanguagesparagraphs
```

239 Exercise 2 Sentiment Analysis on movie reviews

- Write a text classification pipeline to classify movie reviews as either positive or negative
- Find a good set of parameters using grid search
- Evaluate the performance on a held out test set

ipython command line

```
run workspaceexercise02sentimentpy datamoviereviewstxtsentoken
```

2310 Exercise 3 CLI text classification utility

Using the results of the previous exercises and the cPickle module of the standard library write a command line utility that detects the language of some text provided on stdin and estimate the polarity positive or negative if the text is written in English

Bonus point if the utility is able to give a confidence level for its predictions

2311 Where to from here

Here are a few suggestions to help further your scikitlearn intuition upon the completion of this tutorial

- Try playing around with the analyzer and token normalisation under CountVectorizer
- If you don't have labels try using Clustering on your problem
- If you have multiple labels per document eg categories have a look at the Multiclass and multilabel section
- Try using Truncated SVD for latent semantic analysis
- Have a look at using Outofcore Classification to learn from data that would not fit into the computer main memory
- Have a look at the Hashing Vectorizer as a memory efficient alternative to CountVectorizer

24 Choosing the right estimator

Often the hardest part of solving a machine learning problem can be finding the right estimator for the job

Different estimators are better suited for different types of data and different problems

The flowchart below is designed to give users a bit of a rough guide on how to approach problems with regard to which estimators to try on your data

24 Choosing the right estimator 193

scikitlearn user guide Release 0213

CHAPTER

THREE

USER GUIDE

31 Supervised learning

311 Generalized Linear Models

The following are a set of methods intended for regression in which the target value is expected to be a linear combination of the features In mathematical notation if \hat{y} is the predicted value

$\hat{y} = \beta_0 + \beta_1 x_1 + \dots + \beta_n x_n$

Across the module we designate the vector $\beta = [\beta_0, \beta_1, \dots, \beta_n]$ as `coef` and β_0 as `intercept`

To perform classification with generalized linear models see Logistic regression

Ordinary Least Squares

`LinearRegression` fits a linear model with coefficients $\beta_0, \beta_1, \dots, \beta_n$ to minimize the residual sum of squares between the observed targets in the dataset and the targets predicted by the linear approximation Mathematically it solves a problem of the form

$$\min_{\beta} \sum_{i=1}^n (y_i - \hat{y}_i)^2$$

`LinearRegression` will take in its `fit` method arrays `X` `y` and will store the coefficients β of the linear model in its `coef` member

```
scikitlearn user guide Release 0.21.3
from sklearn import linear_model
reg = linear_model.LinearRegression()
reg.fit(X, y)
```

```
LinearRegression(copy_X=True, fit_intercept=True, n_jobs=None,
normalize=False,
reg_coef=0.05)
```

The coefficient estimates for Ordinary Least Squares rely on the independence of the features. When features are correlated and the columns of the design matrix X have an approximate linear dependence, the design matrix becomes close to singular and as a result the least squares estimate becomes highly sensitive to random errors in the observed target, producing a large variance. This situation of multicollinearity can arise, for example, when data are collected without an experimental design.

- Examples
- Linear Regression Example
- Ordinary Least Squares Complexity

The least squares solution is computed using the singular value decomposition of X . If X is a matrix of shape $n_{\text{samples}} \times n_{\text{features}}$, this method has a cost of $O(n_{\text{samples}}^2 n_{\text{features}})$ assuming that $n_{\text{samples}} \geq n_{\text{features}}$.

Ridge Regression

Ridge regression addresses some of the problems of Ordinary Least Squares by imposing a penalty on the size of the coefficients. The ridge coefficients minimize a penalized residual sum of squares:

$$\min_{\beta} \|y - X\beta\|^2 + \lambda \|\beta\|^2$$

The complexity parameter $\lambda \geq 0$ controls the amount of shrinkage; the larger the value of λ , the greater the amount of shrinkage, and thus the coefficients become more robust to collinearity.

As with other linear models, Ridge will take in its `fit` method arrays X , y , and will store the coefficients β of the linear model in its `coef` member.

scikitlearn user guide Release 0213

```
from sklearn import linearmodel
```

```
reg = linearmodel.Ridge(alpha=5)
```

```
reg.fit(0 0 0 1 1 0 1 1)
```

```
Ridge(alpha=0.5, copy_X=True, fit_intercept=True, max_iter=None,
```

```
normalize=False, random_state=None, solver='auto', tol=0.001,
```

```
reg.coef
```

```
array(0.34545455 0.34545455
```

```
reg.intercept_
```

```
0.13636
```

Examples

- Plot Ridge coefficients as a function of the regularization

- Classification of text documents using sparse features

Ridge Complexity

This method has the same order of complexity as Ordinary Least Squares

Setting the regularization parameter generalized CrossValidation

RidgeCV implements ridge regression with builtin crossvalidation of the alpha parameter The object works in the same way as GridSearchCV except that it defaults to Generalized CrossValidation GCV an efficient form of leaveoneout crossvalidation

```
import numpy as np
```

```
from sklearn import linearmodel
```

```
reg = linearmodel.RidgeCV(alphas=np.logspace(-6, 6, 13))
```

```
reg.fit(0 0 0 1 1 0 1 1)
```

```
RidgeCV(alphas=[1e-06, 1e-05, 1e-04, 1e-03, 1e-02, 1e-01, 1e00, 1e01,
```

```
1e02, 1e03, 1e04, 1e05, 1e06],
```

```
cv=None, fit_intercept=True, gcv_mode=None, normalize=False,
```

```
scoring=None, store_cv_values=False,
```

```
reg.alpha_
```

```
0.01
```

Specifying the value of the cv attribute will trigger the use of crossvalidation with GridSearchCV for example

cv=10 for 10fold crossvalidation rather than Generalized CrossValidation

Lasso

The Lasso is a linear model that estimates sparse coefficients It is useful in some contexts due to its tendency to prefer solutions with fewer nonzero coefficients effectively reducing the number of features upon which the given solution is dependent For this reason Lasso and its variants are fundamental to the field of compressed sensing

31 Supervised learning 199

scikitlearn user guide Release 0213

Under certain conditions it can recover the exact set of nonzero coefficients see Compressive sensing tomography reconstruction with L1 prior Lasso

Mathematically it consists of a linear model with an added regularization term The objective function to minimize is

$$\min_{\beta} \frac{1}{2} \sum_{i=1}^n \text{samples}_i - \beta^2 + 2\lambda \|\beta\|_1$$

The lasso estimate thus solves the minimization of the leastsquares penalty with $\lambda \|\beta\|_1$ added where λ is a constant and $\|\beta\|_1$ is the ℓ_1 norm of the coefficient vector

The implementation in the class Lasso uses coordinate descent as the algorithm to fit the coefficients See Least Angle Regression for another implementation

```
from sklearn import linearmodel
reg = linearmodel.Lasso(alpha=0.1)
reg.fit(0 0 1 1 0 1)
Lasso(alpha=0.1, copy_X=True, fit_intercept=True, max_iter=1000,
normalize=False, positive=False, precompute=False, random_state=None,
selection=cyclic, tol=0.0001, warm_start=False)
reg.predict(1 1)
array(0.8)
```

The function lassopath is useful for lowerlevel tasks as it computes the coefficients along the full path of possible values

Examples

- Lasso and Elastic Net for Sparse Signals
- Compressive sensing tomography reconstruction with L1 prior Lasso

Note Feature selection with Lasso

As the Lasso regression yields sparse models it can thus be used to perform feature selection as detailed in L1based feature selection

The following two references explain the iterations used in the coordinate descent solver of scikitlearn as well as the duality gap computation used for convergence control

Setting regularization parameter

The alpha parameter controls the degree of sparsity of the estimated coefficients

200 Chapter 3 User Guide

scikitlearn user guide Release 0213

Using crossvalidation

scikitlearn exposes objects that set the Lasso alpha parameter by crossvalidation LassoCV andLassoLarsCV

LassoLarsCV is based on the Least Angle Regression algorithm explained below

For highdimensional datasets with many collinear features LassoCV is most often preferable However

LassoLarsCV has the advantage of exploring more relevant values of alpha parameter and if the number of samples is very small compared to the number of features it is often faster than LassoCV

Informationcriteria based model selection

Alternatively the estimator LassoLarsIC proposes to use the Akaike information criterion AIC and the Bayes

Information criterion BIC It is a computationally cheaper alternative to find the optimal value of alpha as the regu

larization path is computed only once instead of k1 times when using kfold crossvalidation However such criteria

needs a proper estimation of the degrees of freedom of the solution are derived for large samples asymptotic results

and assume the model is correct ie that the data are actually generated by this model They also tend to break when

the problem is badly conditioned more features than samples

Examples

•Lasso model selection CrossValidation AIC BIC

31 Supervised learning 201

scikitlearn user guide Release 0213

Comparison with the regularization parameter of SVM (Support Vector Machine)

The equivalence between α and the regularization parameter of SVM (Support Vector Machine) C is given by $\alpha = 1/C$ or $\alpha = 1/(n \cdot \text{samples} \cdot C)$ depending on the estimator and the exact objective function optimized by the model

Multitask Lasso

The `MultiTaskLasso` is a linear model that estimates sparse coefficients for multiple regression problems jointly. y is a 2D array of shape $(n_{\text{samples}}, n_{\text{tasks}})$. The constraint is that the selected features are the same for all the regression problems also called tasks

The following figure compares the location of the nonzero entries in the coefficient matrix W obtained with a simple Lasso or a `MultiTaskLasso`. The Lasso estimates yield scattered nonzeros while the nonzeros of the `MultiTaskLasso` are full columns

Fitting a timeseries model imposing that any active feature be active at all times

Examples

- Joint feature selection with multitask Lasso

Mathematically it consists of a linear model trained with a mixed ℓ_1/ℓ_2 norm for regularization. The objective function

202 Chapter 3 User Guide

to minimize is

min

$\frac{1}{2}$

$\sum_{i=1}^n \text{samples}_i - \frac{1}{2}$

Fro^2

where Fro indicates the Frobenius norm

$\text{Fro} \sqrt{\sum}$

\sum^2

\sum

and l_1/l_2 reads

$\frac{1}{2} \sum$

$\sqrt{\sum}$

\sum^2

\sum

The implementation in the class MultiTaskLasso uses coordinate descent as the algorithm to fit the coefficients

ElasticNet

ElasticNet is a linear regression model trained with both l_1 and l_2 norm regularization of the coefficients This combination allows for learning a sparse model where few of the weights are nonzero like Lasso while still maintaining the regularization properties of Ridge We control the convex combination of l_1 and l_2 using the l_1 ratio parameter

Elasticnet is useful when there are multiple features which are correlated with one another Lasso is likely to pick one of these at random while elasticnet is likely to pick both

A practical advantage of trading off between Lasso and Ridge is that it allows ElasticNet to inherit some of Ridge's stability under rotation

The objective function to minimize is in this case

min

$\frac{1}{2}$

$\sum_{i=1}^n \text{samples}_i - \frac{1}{2}$

$\sum \alpha \sum^2$

\sum^2

\sum

The class ElasticNetCV can be used to set the parameters α and l_1 ratio α by crossvalidation

scikitlearn user guide Release 0213

Examples

- Lasso and Elastic Net for Sparse Signals
- Lasso and Elastic Net

The following two references explain the iterations used in the coordinate descent solver of scikitlearn as well as the duality gap computation used for convergence control

References

- “Regularization Path For Generalized linear Models by Coordinate Descent” Friedman Hastie Tibshirani J Stat Softw 2010 Paper
- “An InteriorPoint Method for LargeScale L1Regularized Least Squares” S J Kim K Koh M Lustig S Boyd and D Gorinevsky in IEEE Journal of Selected Topics in Signal Processing 2007 Paper

Multitask ElasticNet

TheMultiTaskElasticNet is an elasticnet model that estimates sparse coefficients for multiple regression problems jointly Y is a 2D array of shape nsamples ntasks The constraint is that the selected features are the same for all the regression problems also called tasks

Mathematically it consists of a linear model trained with a mixed ℓ_1/ℓ_2 norm and ℓ_2 norm for regularization The objective function to minimize is

$$\min_{\beta} \frac{1}{2} \sum_{i=1}^n \text{samples}_i - \frac{1}{2} \sum_{j=1}^n \text{tasks}_j^2 + \lambda \left(\sum_{j=1}^n \|\beta_j\|_1 + \frac{1}{2} \sum_{j=1}^n \|\beta_j\|_2^2 \right)$$

The implementation in the class MultiTaskElasticNet uses coordinate descent as the algorithm to fit the coefficients

The classMultiTaskElasticNetCV can be used to set the parameters alpha andl1ratio by cross validation

Least Angle Regression

Leastangle regression LARS is a regression algorithm for highdimensional data developed by Bradley Efron Trevor Hastie Iain Johnstone and Robert Tibshirani LARS is similar to forward stepwise regression At each step it finds the feature most correlated with the target When there are multiple features having equal correlation instead of continuing along the same feature it proceeds in a direction equiangular between the features

The advantages of LARS are

- It is numerically efficient in contexts where the number of features is significantly greater than the number of samples
- It is computationally just as fast as forward selection and has the same order of complexity as ordinary least squares
- It produces a full piecewise linear solution path which is useful in crossvalidation or similar attempts to tune the model
- If two features are almost equally correlated with the target then their coefficients should increase at approximately the same rate The algorithm thus behaves as intuition would expect and also is more stable

scikitlearn user guide Release 0213

- It is easily modified to produce solutions for other estimators like the Lasso

The disadvantages of the LARS method include

- Because LARS is based upon an iterative refitting of the residuals it would appear to be especially sensitive to the effects of noise This problem is discussed in detail by Weisberg in the discussion section of the Efron et al 2004 Annals of Statistics article

The LARS model can be used using estimator `Lars` or its lowlevel implementation `larspath` or

`larspathgram`

`LARS Lasso`

`LassoLars` is a lasso model implemented using the LARS algorithm and unlike the implementation based on coordinate descent this yields the exact solution which is piecewise linear as a function of the norm of its coefficients

```
from sklearn import linearmodel
```

```
reg = linearmodel.LassoLars(alpha=1
```

```
regfit0 0 1 1 0 1
```

```
LassoLars(alpha=0.1, copy_X=True, eps=fit_intercept=True
```

```
fit_path=True, max_iter=500, normalize=True, positive=False
```

```
precompute=None, verbose=False
```

```
reg.coef
```

```
array(0.717157, 0)
```

Examples

- Lasso path using LARS

The `Lars` algorithm provides the full path of the coefficients along the regularization parameter almost for free thus a common operation is to retrieve the path with one of the functions `larspath` or `larspathgram`

Mathematical formulation

The algorithm is similar to forward stepwise regression but instead of including features at each step the estimated coefficients are increased in a direction equiangular to each one's correlations with the residual

31 Supervised learning 205

Instead of giving a vector result the LARS solution consists of a curve denoting the solution for each value of the ℓ_1 norm of the parameter vector. The full coefficients path is stored in the array `coefpath` which has size `nfeatures`. The first column is always zero.

References

- Original Algorithm is detailed in the paper Least Angle Regression by Hastie et al

Orthogonal Matching Pursuit OMP

`OrthogonalMatchingPursuit` and `orthogonalmp` implements the OMP algorithm for approximating the fit of a linear model with constraints imposed on the number of nonzero coefficients ie the ℓ_0 pseudonorm

Being a forward feature selection method like Least Angle Regression, orthogonal matching pursuit can approximate the optimum solution vector with a fixed number of nonzero elements

$$\arg \min$$

$$\|y - X\beta\|_2^2$$

$$\text{subject to } 0 \leq \|\beta\|_0 \leq \text{nonzero_coefs}$$

Alternatively orthogonal matching pursuit can target a specific error instead of a specific number of nonzero coefficients. This can be expressed as

$$\arg \min$$

$$\|y - X\beta\|_2^2$$

$$\text{subject to } \|\beta\|_0 \leq \text{tol}$$

OMP is based on a greedy algorithm that includes at each step the atom most highly correlated with the current residual. It is similar to the simpler matching pursuit (MP) method but better in that at each iteration the residual is recomputed using an orthogonal projection on the space of the previously chosen dictionary elements.

Examples

- `Orthogonal Matching Pursuit`

- Matching pursuits with time-frequency dictionaries S. G. Mallat, Z. Zhang

Bayesian Regression

Bayesian regression techniques can be used to include regularization parameters in the estimation procedure. The regularization parameter is not set in a hard sense but tuned to the data at hand.

This can be done by introducing uninformative priors over the hyper parameters of the model. The ℓ_2 regularization used in Ridge Regression is equivalent to finding a maximum a posteriori estimation under a Gaussian prior over the coefficients β with precision λ^{-1} . Instead of setting λ manually it is possible to treat it as a random variable to be estimated from the data.

To obtain a fully probabilistic model the output y is assumed to be Gaussian distributed around $X\beta$.

$$y \sim \mathcal{N}(X\beta, \sigma^2 I)$$

scikitlearn user guide Release 0.21.3

where β is again treated as a random variable that is to be estimated from the data

The advantages of Bayesian Regression are

- It adapts to the data at hand
- It can be used to include regularization parameters in the estimation procedure

The disadvantages of Bayesian regression include

- Inference of the model can be time consuming

References

- A good introduction to Bayesian methods is given in C Bishop Pattern Recognition and Machine learning
- Original Algorithm is detailed in the book Bayesian learning for neural networks by Radford M Neal

Bayesian Ridge Regression

BayesianRidge estimates a probabilistic model of the regression problem as described above. The prior for the coefficient β is given by a spherical Gaussian

$$p(\beta) \propto \exp\left(-\frac{1}{2}\beta^T\Lambda\beta\right)$$

The priors over α and σ^2 are chosen to be gamma distributions the conjugate prior for the precision of the Gaussian

The resulting model is called Bayesian Ridge Regression and is similar to the classical Ridge

The parameters α and σ^2 are estimated jointly during the fit of the model the regularization parameters α and σ^2 being estimated by maximizing the log marginal likelihood. The scikitlearn implementation is based on the algorithm described in Appendix A of Tipping 2001 where the update of the parameters α and σ^2 is done as suggested in MacKay 1992.

The remaining hyperparameters are the parameters α_1 and α_2 of the gamma priors over α and σ^2 . These are usually chosen to be noninformative. By default $\alpha_1 = 10^{-6}$ and $\alpha_2 = 10^{-6}$.

Bayesian Ridge Regression is used for regression

scikitlearn user guide Release 0213

```
from sklearn import linearmodel
```

```
X = [[0, 0, 1, 1, 2, 2, 3, 3]
```

```
Y = [0, 1, 2, 3]
```

```
reg = linearmodel.BayesianRidge
```

```
reg.fit(X, Y)
```

```
BayesianRidge(alpha=1e-06, alpha2=1e-06, compute_score=False, copy_X=True,
```

```
fit_intercept=True, lambda_1=1e-06, lambda_2=1e-06, n_iter=300,
```

```
normalize=False, tol=0.001, verbose=False)
```

After being fitted the model can then be used to predict new values

```
reg.predict([1, 0])
```

```
array([0.5, 0.0000013])
```

The coefficients of the model can be accessed

```
reg.coef_
```

```
array([0.499999993, 0.499999993])
```

Due to the Bayesian framework the weights found are slightly different to the ones found by Ordinary Least Squares

However Bayesian Ridge Regression is more robust to illposed problems

Examples

- Bayesian Ridge Regression

References

- Section 33 in Christopher M Bishop Pattern Recognition and Machine Learning 2006

Automatic Relevance Determination (ARD)

ARDRegression is very similar to Bayesian Ridge Regression but can lead to sparser coefficients

ARDRegression poses a different prior over β by dropping the assumption of the Gaussian being spherical

Instead the distribution over β is assumed to be an axisparallel elliptical Gaussian distribution

This means each coefficient β_j is drawn from a Gaussian distribution centered on zero and with a precision λ_j

$\lambda_j \sim \text{Gamma}(\alpha, \beta)$

with $\text{diag}(\lambda) = \text{diag}(\lambda_1, \dots, \lambda_p)$

In contrast to Bayesian Ridge Regression each coordinate of β has its own standard deviation λ_j . The prior over all

β is chosen to be the same gamma distribution given by hyperparameters α and β

ARD is also known in the literature as Sparse Bayesian Learning and Relevance Vector Machine

References

Logistic regression

Logistic regression despite its name is a linear model for classification rather than regression Logistic regression is also known in the literature as logit regression maximumentropy classification MaxEnt or the loglinear classifier In this model the probabilities describing the possible outcomes of a single trial are modeled using a logistic function Logistic regression is implemented in LogisticRegression This implementation can fit binary OnevsRest or multinomial logistic regression with optional ℓ_1 / ℓ_2 or ElasticNet regularization Note Regularization is applied by default which is common in machine learning but not in statistics Another advantage of regularization is that it improves numerical stability No regularization amounts to setting C to a very high value

As an optimization problem binary class ℓ_2 penalized logistic regression minimizes the following cost function

$$\min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w}\|_2^2 - \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i) + \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i)$$

Similarly ℓ_1 regularized logistic regression solves the following optimization problem

$$\min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w}\|_1 - \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i) + \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i)$$

ElasticNet regularization is a combination of ℓ_1 and ℓ_2 and minimizes the following cost function

$$\min_{\mathbf{w}} \frac{1}{2} \|\mathbf{w}\|_2^2 + \lambda \|\mathbf{w}\|_1 - \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i) + \sum_{i=1}^n \log \exp(\mathbf{w}^T \mathbf{x}_i)$$

where α controls the strength of l_1 regularization vs l_2 regularization it corresponds to the `l1_ratio` parameter

Note that in this notation it's assumed that the target y takes values in the set $\{-1, 1\}$ at trial i . We can also see that ElasticNet is equivalent to l_1 when $\alpha = 1$ and equivalent to l_2 when $\alpha = 0$

The solvers implemented in the class `LogisticRegression` are "liblinear" "newtoncg" "lbfgs" "sag" and "saga"

The solver "liblinear" uses a coordinate descent CD algorithm and relies on the excellent C LIBLINEAR library which is shipped with scikitlearn. However the CD algorithm implemented in liblinear cannot learn a true multinomial multiclass model instead the optimization problem is decomposed in a "onevsrest" fashion so separate binary classifiers are trained for all classes. This happens under the hood so `LogisticRegression` instances using this solver behave as multiclass classifiers. For l_1 regularization `sklearnsvm.l1minc` allows to calculate the lower bound for C in order to get a non "null" all feature weights to zero model.

The "lbfgs" "sag" and "newtoncg" solvers only support l_2 regularization or no regularization and are found to converge faster for some highdimensional data. Setting multiclass to "multinomial" with these solvers learns a true multinomial logistic regression model⁵ which means that its probability estimates should be better calibrated than the default "onevsrest" setting.

The "sag" solver uses Stochastic Average Gradient descent⁶. It is faster than other solvers for large datasets when both the number of samples and the number of features are large.

The "saga" solver⁷ is a variant of "sag" that also supports the nonsmooth penalty l_1 . This is therefore the solver of choice for sparse multinomial logistic regression. It is also the only solver that supports `penalty=elasticnet`.

The "lbfgs" is an optimization algorithm that approximates the Broyden-Fletcher-Goldfarb-Shanno algorithm⁸ which belongs to quasi-Newton methods. The "lbfgs" solver is recommended for use for small datasets but for larger datasets its performance suffers⁹.

The following table summarizes the penalties supported by each solver.

| Solvers | Penalties | 'liblinear' | 'lbfgs' | 'newtoncg' | 'sag' | 'saga' |
|-------------|---------------|-------------|---------|------------|-------|--------|
| Multinomial | L_2 penalty | no | yes | yes | yes | yes |
| OVR | L_2 penalty | yes | yes | yes | yes | yes |
| Multinomial | L_1 penalty | no | no | no | no | yes |
| OVR | L_1 penalty | yes | no | no | no | yes |
| ElasticNet | no | no | no | no | yes | |
| No penalty | 'none' | no | yes | yes | yes | yes |

Behaviors

| | | | | | | |
|-----------------------------|-----|-----|-----|-----|-----|----|
| Penalize the intercept | bad | yes | no | no | no | no |
| Faster for large datasets | no | no | no | yes | yes | |
| Robust to unscaled datasets | yes | yes | yes | no | no | |

The "lbfgs" solver is used by default for its robustness. For large datasets the "saga" solver is usually faster. For large dataset you may also consider using `SGDClassifier` with 'log' loss which might be even faster but requires more tuning.

- Multiclass sparse logisitic regression on newgroups20
- MNIST classification using multinomial logistic L1

Differences from liblinear

There might be a difference in the scores obtained between LogisticRegression withsolverliblinear orLinearSVC and the external liblinear library directly when fitinterceptFalse and the fit coef or the data to be predicted are zeroes This is because for the samples with decisionfunction zero LogisticRegression andLinearSVC predict the negative class while liblinear predicts the positive class Note that a model with fitinterceptFalse and having many samples with decisionfunction zero is likely to be a underfit bad model and you are advised to set fitinterceptTrue and increase the inter ceptscaling

Note Feature selection with sparse logistic regression

A logistic regression with l1penalty yields sparse models and can thus be used to perform feature selection as detailed in L1based feature selection

LogisticRegressionCV implements Logistic Regression with builtin crossvalidation support to find the opti malCandl1ratio parameters according to the scoring attribute The “newtoncg” “sag” “saga” and “lbfgs” solvers are found to be faster for highdimensional dense data due to warmstarting see Glossary

Perceptron

The Perceptron is another simple classification algorithm suitable for large scale learning. By default

- It does not require a learning rate
- It is not regularized/penalized
- It updates its model only on mistakes

The last characteristic implies that the Perceptron is slightly faster to train than SGD with the hinge loss and that the resulting models are sparser.

Passive Aggressive Algorithms

The passive aggressive algorithms are a family of algorithms for large scale learning. They are similar to the Perceptron in that they do not require a learning rate. However, contrary to the Perceptron, they include a regularization parameter C .

For classification, `PassiveAggressiveClassifier` can be used with `loss=hinge` (PAI) or `loss=squared_hinge` (PAII). For regression, `PassiveAggressiveRegressor` can be used with `loss=epsilon_insensitive` (PAI) or `loss=squared_epsilon_insensitive` (PAII).

Robustness: regression, outliers and modeling errors

Robust regression aims to fit a regression model in the presence of corrupt data, either outliers or error in the model. Different scenarios and useful concepts.

There are different things to keep in mind when dealing with data corrupted by outliers.

scikitlearn user guide Release 0213

- Outliers in X or in y
- Outliers in the y direction Outliers in the X direction
- Fraction of outliers versus amplitude of error

The number of outlying points matters but also how much they are outliers

Small outliers Large outliers

An important notion of robust fitting is that of breakdown point the fraction of data that can be outlying for the fit to start missing the inlying data

Note that in general robust fitting in highdimensional setting large nfeatures is very hard The robust models here will probably not work in these settings

Tradeoffs which estimator

Scikitlearn provides 3 robust regression estimators RANSAC Theil Sen andHuberRegressor

- HuberRegressor should be faster than RANSAC andTheil Sen unless the number of samples are very large ie nsamples nfeatures This is because RANSAC andTheil Sen fit on smaller subsets of the data However both Theil Sen andRANSAC are unlikely to be as robust as HuberRegressor for the default parameters

31 Supervised learning 213

scikitlearn user guide Release 0213

- RANSAC is faster than Theil Sen and scales much better with the number of samples
- RANSAC will deal better with large outliers in the y direction most common situation
- Theil Sen will cope better with mediusize outliers in the X direction but this property will disappear in highdimensional settings

When in doubt use RANSAC

RANSAC RANdom SAmple Consensus

RANSAC RANdom SAmple Consensus fits a model from random subsets of inliers from the complete data set

RANSAC is a nondeterministic algorithm producing only a reasonable result with a certain probability which is dependent on the number of iterations see maxtrials parameter It is typically used for linear and nonlinear regression problems and is especially popular in the field of photogrammetric computer vision

The algorithm splits the complete input sample data into a set of inliers which may be subject to noise and outliers which are eg caused by erroneous measurements or invalid hypotheses about the data The resulting model is then estimated only from the determined inliers

Details of the algorithm

Each iteration performs the following steps

1 Selectminsamples random samples from the original data and check whether the set of data is valid see isdatavalid

2 Fit a model to the random subset baseestimatorfit and check whether the estimated model is valid seeismodelvalid

3 Classify all data as inliers or outliers by calculating the residuals to the estimated model baseestimator predictX y all data samples with absolute residuals smaller than the residualthreshold are considered as inliers

4 Save fitted model as best model if number of inlier samples is maximal In case the current estimated model has the same number of inliers it is only considered as the best model if it has better score

scikitlearn user guide Release 0213

These steps are performed either a maximum number of times `maxtrials` or until one of the special stop criteria are met see `stopninliers` and `stopscore`. The final model is estimated using all inlier samples consensus set of the previously determined best model

The `isdatavalid` and `ismodelvalid` functions allow to identify and reject degenerate combinations of random subsamples. If the estimated model is not needed for identifying degenerate cases `isdatavalid` should be used as it is called prior to fitting the model and thus leading to better computational performance

TheilSen estimator generalized median based estimator

The TheilSenRegressor estimator uses a generalization of the median in multiple dimensions. It is thus robust to multivariate outliers. Note however that the robustness of the estimator decreases quickly with the dimensionality of the problem. It loses its robustness properties and becomes no better than an ordinary least squares in high dimension

- Examples
- TheilSen Regression
 - Robust linear estimator fitting

References

- https://en.wikipedia.org/wiki/Theil%E2%80%93S%C3%A9n_estimator

Theoretical considerations

TheilSenRegressor is comparable to the Ordinary Least Squares (OLS) in terms of asymptotic efficiency and as an unbiased estimator. In contrast to OLS, TheilSen is a nonparametric method which means it makes no assumption about the underlying distribution of the data. Since TheilSen is a median based estimator, it is more robust against corrupted data aka outliers. In univariate setting, TheilSen has a breakdown point of about 29.3% in case of a simple linear regression which means that it can tolerate arbitrary corrupted data of up to 29.3%.

31 Supervised learning 215

scikitlearn user guide Release 0213

The implementation of TheilSenRegressor in scikitlearn follows a generalization to a multivariate linear regression model using the spatial median which is a generalization of the median to multiple dimensions. In terms of time and space complexity TheilSen scales according to

\sqrt{n} samples
 \sqrt{n} subsamples
which makes it infeasible to be applied exhaustively to problems with a large number of samples and features. Therefore the magnitude of a subpopulation can be chosen to limit the time and space complexity by considering only a random subset of all possible combinations.

Examples
•TheilSen Regression

References

Huber Regression

TheHuberRegressor is different to Ridge because it applies a linear loss to samples that are classified as outliers. A sample is classified as an inlier if the absolute error of that sample is lesser than a certain threshold. It differs from TheilSenRegressor andRANSACRegressor because it does not ignore the effect of the outliers but gives a lesser weight to them.

The loss function that HuberRegressor minimizes is given by

$$\min_{\beta} \sum_{i=1}^n \rho(r_i)$$
$$\rho(r) = \begin{cases} \frac{1}{2}r^2 & \text{if } |r| \leq c \\ c|r| - \frac{1}{2}c^2 & \text{if } |r| > c \end{cases}$$

where $c = \sqrt{2}$

where

ϵ

ϵ^2 if $\epsilon > 2$

$2\epsilon - \epsilon^2$ otherwise

It is advised to set the parameter epsilon to 1.35 to achieve 95 statistical efficiency

Notes

The HuberRegressor differs from using SGDRegressor with loss set to huber in the following ways

- HuberRegressor is scaling invariant. Once epsilon is set, scaling X and y down or up by different values would produce the same robustness to outliers as before, as compared to SGDRegressor where epsilon has to be set again when X and y are scaled.
- HuberRegressor should be more efficient to use on data with small number of samples while SGDRegressor needs a number of passes on the training data to produce the same robustness.

Examples

- HuberRegressor vs Ridge on dataset with strong outliers

References

- Peter J. Huber, Elvezio M. Ronchetti, Robust Statistics, Concomitant scale estimates, pg. 172

Note that this estimator is different from the R implementation of Robust Regression <http://www.stat.columbia.edu/robust/> because the R implementation does a weighted least squares implementation with weights given to each sample on the basis of how much the residual is greater than a certain threshold.

Polynomial regression extending linear models with basis functions

One common pattern within machine learning is to use linear models trained on nonlinear functions of the data. This approach maintains the generally fast performance of linear methods while allowing them to fit a much wider range of data.

31 Supervised learning 217

scikitlearn user guide Release 0213

For example a simple linear regression can be extended by constructing polynomial features from the coefficients
In the standard linear regression case you might have a model that looks like this for twodimensional data

$$y = \theta_0 + \theta_1 x_1 + \theta_2 x_2$$

If we want to fit a paraboloid to the data instead of a plane we can combine the features in secondorder polynomials
so that the model looks like this

$$y = \theta_0 + \theta_1 x_1 + \theta_2 x_2 + \theta_3 x_1^2 + \theta_4 x_2^2 + \theta_5 x_1 x_2$$

The sometimes surprising observation is that this is still a linear model to see this imagine creating a new set of
features

$$\begin{bmatrix} 1 & x_1 & x_2 & x_1^2 & x_2^2 & x_1 x_2 \end{bmatrix}$$

With this relabeling of the data our problem can be written

$$y = \theta_0 + \theta_1 x_1 + \theta_2 x_2 + \theta_3 x_1^2 + \theta_4 x_2^2 + \theta_5 x_1 x_2$$

We see that the resulting polynomial regression is in the same class of linear models we considered above ie the
model is linear in θ and can be solved by the same techniques By considering linear fits within a higherdimensional
space built with these basis functions the model has the flexibility to fit a much broader range of data

Here is an example of applying this idea to onedimensional data using polynomial features of varying degrees

This figure is created using the PolynomialFeatures transformer which transforms an input data matrix into a
new data matrix of a given degree It can be used as follows

```
from sklearn.preprocessing import PolynomialFeatures
import numpy as np
X = np.arange(6).reshape(3, 2)
```

```
X
array([[0, 1],
       [2, 3],
       [4, 5]])
poly = PolynomialFeatures(degree=2)
poly.fit_transform(X)
array([[1, 0, 1, 0, 0, 1],
       [1, 2, 3, 4, 6, 9],
       [1, 4, 5, 16, 20, 25]])
```

scikitlearn user guide Release 0213

The features of X have been transformed from $\begin{bmatrix} 1 & 2 \\ 1 & 2 \end{bmatrix}$ to $\begin{bmatrix} 1 & 2 & 1 \\ 1 & 2 & 4 \end{bmatrix}$

$\begin{bmatrix} 1 & 2 \\ 1 & 2 \end{bmatrix}$

2 and can now be used within any

linear model

This sort of preprocessing can be streamlined with the Pipeline tools A single object representing a simple polynomial

regression can be created and used as follows

```
from sklearn.preprocessing import PolynomialFeatures
```

```
from sklearn.linear_model import LinearRegression
```

```
from sklearn.pipeline import Pipeline
```

```
import numpy as np
```

```
model = Pipeline([PolynomialFeatures(degree=3,
```

```
linear=LinearRegression(fit_intercept=False,
```

```
fit_to_an_order_3_polynomial_data
```

```
x=np.arange(5,
```

```
y=[3, 2, x**2, x**3,
```

```
model=model.fit(x, np.newaxis * y)
```

```
model.named_steps['linear'].coef_
```

```
array([ 3.  2.  1.  1.]
```

The linear model trained on polynomial features is able to exactly recover the input polynomial coefficients

In some cases it's not necessary to include higher powers of any single feature but only the so called interaction

features that multiply together at most ≤ 2 distinct features These can be gotten from PolynomialFeatures with

the setting `interaction_only=True`

For example when dealing with boolean features $\begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}$

$\begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}$ for all $\begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}$ and is therefore useless but $\begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}$ represents the

conjunction of two booleans This way we can solve the XOR problem with a linear classifier

```
from sklearn.linear_model import Perceptron
```

```
from sklearn.preprocessing import PolynomialFeatures
```

```
import numpy as np
```

```
X=np.array([0, 0, 1, 1, 0, 1, 1])
```

```
y=[X[0], X[1],
```

```
0, 1, 0, 1, 0]
```

```
X=PolynomialFeatures(interaction_only=True).fit_transform(X).astype(int)
```

```
X
```

```
array([ 0,  0,  0,  0,
```

```
1,  0,  1,  0,
```

```
1,  1,  0,  0,
```

```
1,  1,  1,  1])
```

```
clf=Perceptron(fit_intercept=False, max_iter=10, tol=None,
```

```
shuffle=False).fit(X, y)
```

And the classifier "predictions" are perfect

```
clf.predict(X)
```

```
array([ 0,  1,  1,  0,
```

```
0,  1,  1,  0])
```

```
clf.score(X, y)
```

```
1.0
```

312 Linear and Quadratic Discriminant Analysis

Linear Discriminant Analysis `discriminantanalysis.LinearDiscriminantAnalysis` and

Quadratic Discriminant Analysis `discriminantanalysis.QuadraticDiscriminantAnalysis`

are two classic classifiers with as their names suggest a linear and a quadratic decision surface respectively

31 Supervised learning 219

scikitlearn user guide Release 0213

These classifiers are attractive because they have closedform solutions that can be easily computed are inherently multiclass have proven to work well in practice and have no hyperparameters to tune

The plot shows decision boundaries for Linear Discriminant Analysis and Quadratic Discriminant Analysis The bottom row demonstrates that Linear Discriminant Analysis can only learn linear boundaries while Quadratic Discriminant Analysis can learn quadratic boundaries and is therefore more flexible

Examples

Linear and Quadratic Discriminant Analysis with covariance ellipsoid Comparison of LDA and QDA on synthetic data

Dimensionality reduction using Linear Discriminant Analysis

discriminantanalysisLinearDiscriminantAnalysis can be used to perform supervised dimensionality reduction by projecting the input data to a linear subspace consisting of the directions which maximize the separation between classes in a precise sense discussed in the mathematics section below The dimension of the output is necessarily less than the number of classes so this is in general a rather strong dimensionality reduction and only makes sense in a multiclass setting

220 Chapter 3 User Guide

scikitlearn user guide Release 0213

This is implemented in `discriminantanalysisLinearDiscriminantAnalysis` transform. The desired dimensionality can be set using the `ncomponents` constructor parameter. This parameter has no influence on `discriminantanalysisLinearDiscriminantAnalysis` fit or `discriminantanalysisLinearDiscriminantAnalysis` predict.

Examples

Comparison of LDA and PCA (Principal Component Analysis) 2D projection of Iris dataset. Comparison of LDA and PCA (Principal Component Analysis) reduction of the Iris dataset.

Mathematical formulation of the LDA and QDA classifiers

Both LDA and QDA can be derived from simple probabilistic models which model the class conditional distribution of the data \mathbf{x} for each class ω . Predictions can then be obtained by using Bayes' rule

$$p(\omega|\mathbf{x}) = \frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x})}$$

$$p(\mathbf{x}|\omega) = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\}$$

$$p(\omega) = \frac{1}{N_\omega}$$

and we select the class ω which maximizes this conditional probability

More specifically for linear and quadratic discriminant analysis \mathbf{x} is modeled as a multivariate Gaussian distribution with density

$$p(\mathbf{x}|\omega) = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\}$$

$$p(\omega) = \frac{1}{N_\omega}$$

$$p(\omega|\mathbf{x}) = \frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x})}$$

$$p(\omega|\mathbf{x}) = \frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x})}$$

where D is the number of features

To use this model as a classifier we just need to estimate from the training data the class priors $p(\omega)$ by the proportion of instances of class ω , the class means μ by the empirical sample class means and the covariance matrices either by the empirical sample class covariance matrices or by a regularized estimator see the section on shrinkage below.

In the case of LDA the Gaussians for each class are assumed to share the same covariance matrix Σ for all ω . This leads to linear decision surfaces which can be seen by comparing the logprobability ratios $\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})}$

$$\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})} = \log\frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x}|\omega')p(\omega')}$$

$$\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})} = \log\frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x}|\omega')p(\omega')}$$

$$\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})} = \log\frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x}|\omega')p(\omega')}$$

$$\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})} = \log\frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x}|\omega')p(\omega')}$$

$$\log\frac{p(\omega|\mathbf{x})}{p(\omega'|\mathbf{x})} = \log\frac{p(\mathbf{x}|\omega)p(\omega)}{p(\mathbf{x}|\omega')p(\omega')}$$

$$0 \Leftrightarrow$$

$$\frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\} \frac{1}{N_\omega} = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu')^\top \Sigma^{-1}(\mathbf{x}-\mu')\right\} \frac{1}{N_{\omega'}}$$

$$\frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\} \frac{1}{N_\omega} = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu')^\top \Sigma^{-1}(\mathbf{x}-\mu')\right\} \frac{1}{N_{\omega'}}$$

$$\frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\} \frac{1}{N_\omega} = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu')^\top \Sigma^{-1}(\mathbf{x}-\mu')\right\} \frac{1}{N_{\omega'}}$$

$$\frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\} \frac{1}{N_\omega} = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu')^\top \Sigma^{-1}(\mathbf{x}-\mu')\right\} \frac{1}{N_{\omega'}}$$

$$\frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu)^\top \Sigma^{-1}(\mathbf{x}-\mu)\right\} \frac{1}{N_\omega} = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{-\frac{1}{2}(\mathbf{x}-\mu')^\top \Sigma^{-1}(\mathbf{x}-\mu')\right\} \frac{1}{N_{\omega'}}$$

In the case of QDA there are no assumptions on the covariance matrices Σ of the Gaussians leading to quadratic decision surfaces. See 3 for more details.

Note Relation with Gaussian Naive Bayes

If in the QDA model one assumes that the covariance matrices are diagonal then the inputs are assumed to be conditionally independent in each class and the resulting classifier is equivalent to the Gaussian Naive Bayes classifier `naivebayesGaussianNB`.

3 "The Elements of Statistical Learning" Hastie T Tibshirani R Friedman J Section 43 p106119 2008

31 Supervised learning 221

Mathematical formulation of LDA dimensionality reduction

To understand the use of LDA in dimensionality reduction it is useful to start with a geometric reformulation of the LDA classification rule explained above We write K for the total number of target classes Since in LDA we assume that all classes have the same estimated covariance Σ we can rescale the data so that this covariance is the identity $\Sigma = I$ with $\tilde{x} = \Sigma^{-1/2}x$

Then one can show that to classify a data point after scaling is equivalent to finding the estimated class mean $\tilde{\mu}_k$ which is closest to the data point in the Euclidean distance But this can be done just as well after projecting on the $(K-1)$ -dimensional affine subspace Π generated by all the $\tilde{\mu}_k$ for all classes This shows that implicit in the LDA classifier there is a dimensionality reduction by linear projection onto a $(K-1)$ -dimensional space

We can reduce the dimension even more to a chosen d by projecting onto the linear subspace Π_d which maximizes the variance of the d components after projection in effect we are doing a form of PCA (Principal Component Analysis) for the transformed class means $\tilde{\mu}_k$

This d corresponds to the `ncomponents` parameter used in the `LinearDiscriminantAnalysis` transform method See [3](#) for more details

Shrinkage
Shrinkage is a tool to improve estimation of covariance matrices in situations where the number of training samples is small compared to the number of features In this scenario the empirical sample covariance is a poor estimator Shrinkage LDA can be used by setting the shrinkage parameter of the `LinearDiscriminantAnalysis` class to 'auto' This automatically determines the optimal shrinkage parameter in an analytic way following the lemma introduced by Ledoit and Wolf⁴ Note that currently shrinkage only works when setting the solver parameter to 'lsqr' or 'eigen'

The shrinkage parameter can also be manually set between 0 and 1 In particular a value of 0 corresponds to no shrinkage which means the empirical covariance matrix will be used and a value of 1 corresponds to complete shrinkage which means that the diagonal matrix of variances will be used as an estimate for the covariance matrix Setting this parameter to a value between these two extrema will estimate a shrunk version of the covariance matrix

⁴Ledoit O Wolf M Honey I Shrank the Sample Covariance Matrix The Journal of Portfolio Management 30(4) 110-119 2004

Estimation algorithms

The default solver is ‘svd’ It can perform both classification and transform and it does not rely on the calculation of the covariance matrix This can be an advantage in situations where the number of features is large However the ‘svd’ solver cannot be used with shrinkage

The ‘lsqr’ solver is an efficient algorithm that only works for classification It supports shrinkage

The ‘eigen’ solver is based on the optimization of the between class scatter to within class scatter ratio It can be used for both classification and transform and it supports shrinkage However the ‘eigen’ solver needs to compute the covariance matrix so it might not be suitable for situations with a high number of features

Examples

Normal and Shrinkage Linear Discriminant Analysis for classification Comparison of LDA classifiers with and without shrinkage

313 Kernel ridge regression

Kernel ridge regression KRR M2012 combines Ridge Regression linear least squares with l2norm regularization with the kernel trick It thus learns a linear function in the space induced by the respective kernel and the data For nonlinear kernels this corresponds to a nonlinear function in the original space

The form of the model learned by KernelRidge is identical to support vector regression SVR (Support Vector Regression) However different loss functions are used KRR uses squared error loss while support vector regression uses ϵ -insensitive loss both combined with l2 regularization In contrast to SVR (Support Vector Regression) fitting KernelRidge can be done in closedform and is typically faster for medium sized datasets On the other hand the learned model is nonsparse and thus slower than SVR (Support Vector Regression) which learns a sparse model for $\epsilon = 0$ at prediction time

The following figure compares KernelRidge and SVR on an artificial dataset which consists of a sinusoidal target function and strong noise added to every fifth datapoint The learned model of KernelRidge and SVR is plotted where both complexity regularization and bandwidth of the RBF (Radial Basis Function) kernel have been optimized using gridsearch The learned functions are very similar however fitting KernelRidge is approx seven times faster than fitting SVR (Support Vector Regression) both with gridsearch However prediction of 100000 target values is more than three times faster with SVR (Support Vector Regression) since it has learned a sparse model using only approx 13 of the 100 training datapoints as support vectors The next figure compares the time for fitting and prediction of KernelRidge and SVR for different sizes of the training set Fitting KernelRidge is faster than SVR (Support Vector Regression) for medium sized training sets less than 1000 samples however for larger training sets SVR (Support Vector Regression) scales better With regard to prediction time SVR (Support Vector Regression) is faster for all sizes of the training set because of the learned sparse solution Note that the degree of sparsity and thus the prediction time depends on the parameters ϵ and γ of the SVR $\epsilon = 0$ would correspond to a dense model

314 Support Vector Machines

Support vector machines SVMs are a set of supervised learning methods used for classification regression and outliers detection

31 Supervised learning 223

scikitlearn user guide Release 0213

The advantages of support vector machines are

- Effective in high dimensional spaces
- Still effective in cases where number of dimensions is greater than the number of samples
- Uses a subset of training points in the decision function called support vectors so it is also memory efficient
- Versatile different Kernel functions can be specified for the decision function Common kernels are provided but it is also possible to specify custom kernels

The disadvantages of support vector machines include

- If the number of features is much greater than the number of samples avoid overfitting in choosing Kernel functions and regularization term is crucial
- SVMs do not directly provide probability estimates these are calculated using an expensive fivefold cross validation see Scores and probabilities below

The support vector machines in scikitlearn support both dense `numpy.ndarray` and convertible to that by `numpy.asarray` and sparse any `scipy.sparse` sample vectors as input However to use an SVM (Support Vector Machine) to make predictions for sparse data it must have been fit on such data For optimal performance use `Cordered numpy.ndarray` dense or `scipy.sparse.csr_matrix` sparse with `dtype=float64`

Classification

`SVC` and `LinearSVC` are classes capable of performing multiclass classification on a dataset

scikitlearn user guide Release 0213

SVC (Support Vector Classification) andNuSVC are similar methods but accept slightly different sets of parameters and have different mathematical formulations see section Mathematical formulation On the other hand LinearSVC is another implementation of Support Vector Classification for the case of a linear kernel Note that LinearSVC does not accept keyword kernel as this is assumed to be linear It also lacks some of the members of SVC (Support Vector Classification) andNuSVC likesupport As other classifiers SVCNuSVC andLinearSVC take as input two arrays an array X of size nsamples nfeatures holding the training samples and an array y of class labels strings or integers size nsamples

```
from sklearn import svm
```

```
X = [[0, 0, 1, 1],
```

```
     [0, 1, 0, 1]]
```

```
y = [0, 1]
```

```
clf = svm.SVC(gamma=scale)
```

```
clf.fit(X, y)
```

```
SVCC10 cachesize=200 class_weight=None coef=0.00
```

```
decision_function_shape='ovr' degree=3 gamma=scale kernel='rbf'
```

```
max_iter=1 probability=False random_state=None shrinking=True
```

```
tol=0.001 verbose=False
```

After being fitted the model can then be used to predict new values

```
clf.predict([2, 2])
```

```
array([1])
```

SVMs decision function depends on some subset of the training data called the support vectors Some properties of

these support vectors can be found in members support_vectors support and n_support

```

Multiclass classification

SVC (Support Vector Classification) andNuSVC implement the “oneagainstone” approach Knerr et al 1990 for multi class classifica

tion If nclass is the number of classes then nclass - 1 - 2 classifiers are con

structed and each one trains data from two classes To provide a consistent interface with other classifiers the

decision_function_shape option allows to monotonically transform the results of the “oneagainstone” classi

fiers to a decision function of shape nsamples nclasses

```
X = [[0, 1, 2, 3],
```

```
     [0, 1, 2, 3]]
```

```
Y = [0, 1, 2, 3]
```

```
clf = svm.SVC(gamma=scale, decision_function_shape='ovo')
```

```
clf.fit(X, Y)
```

```
SVCC10 cachesize=200 class_weight=None coef=0.00
```

```
decision_function_shape='ovo' degree=3 gamma=scale kernel='rbf'
```

```
max_iter=1 probability=False random_state=None shrinking=True
```

```
tol=0.001 verbose=False
```

```
dec_clf.decision_function(1)
```

```
dec_shape[1] = 4 # classes 4 32 6
```

```
6
```

SeeMathematical formulation for a complete description of the decision function

Note that the LinearSVC also implements an alternative multiclass strategy the socalled multiclass SVM (Support Vector Machine) formu

lated by Crammer and Singer by using the option multiclasscrammersinger This method is consis

tent which is not true for onevsrest classification In practice onevsrest classification is usually preferred since

the results are mostly similar but the runtime is significantly less

For “onevsrest” LinearSVC the attributes coef andintercept have the shape nclass

nfeatures andnclass respectively Each row of the coefficients corresponds to one of the nclass

many “onevsrest” classifiers and similar for the intercepts in the order of the “one” class

In the case of “onevsone” SVC (Support Vector Classification) the layout of the attributes is a little more involved In the case of having

a linear kernel the attributes coef andintercept have the shape nclass nclass 1

2 nfeatures andnclass nclass 1 2 respectively This is similar to the layout for

LinearSVC described above with each row now corresponding to a binary classifier The order for classes 0 to n is

“0 vs 1” “0 vs 2” “0 vs n” “1 vs 2” “1 vs 3” “1 vs n” “n1 vs n”

The shape of dualcoef isnclass1 nSV with a somewhat hard to grasp layout The columns corre

spond to the support vectors involved in any of the nclass nclass 1 2 “onevsone” classifiers

Each of the support vectors is used in nclass 1 classifiers The nclass 1 entries in each row correspond

to the dual coefficients for these classifiers

This might be made more clear by an example

Consider a three class problem with class 0 having three support vectors $\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix}$

and class 1 and 2 having two

support vectors $\begin{bmatrix} 1 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 2 \end{bmatrix}$

and $\begin{bmatrix} 1 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 1 \end{bmatrix}$

respectively For each support vector $\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$ there are two dual coefficients Let’s call

the coefficient of support vector $\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 0 \\ 2 \end{bmatrix}$ in the classifier between classes $\begin{bmatrix} 0 \end{bmatrix}$ and $\begin{bmatrix} 1 \end{bmatrix}$ $\begin{bmatrix} 1 \end{bmatrix}$

$\begin{bmatrix} 1 \end{bmatrix}$ Thendualcoef looks like this

$\begin{bmatrix} 0 \\ 0 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}$

Coefficients for SVs of class 0

$\begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 0 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$

Coefficients for SVs of class 1

$\begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 0 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 0 \end{bmatrix}$

Coefficients for SVs of class 2

$\begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 1 \\ 1 \end{bmatrix}$

$\begin{bmatrix} 2 \\ 1 \end{bmatrix}$

228 Chapter 3 User Guide

Scores and probabilities

The `decisionfunction` method of `SVC` and `NuSVC` gives perclass scores for each sample or a single score per sample in the binary case. When the constructor option `probability` is set to `True`, class membership probability estimates from the methods `predict_proba` and `predict_log_proba` are enabled. In the binary case the probabilities are calibrated using Platt scaling (logistic regression on the SVM (Support Vector Machine)'s scores fit by an additional crossvalidation on the training data). In the multiclass case this is extended as per Wu et al 2004. Needless to say the crossvalidation involved in Platt scaling is an expensive operation for large datasets. In addition the probability estimates may be inconsistent with the scores in the sense that the "argmax" of the scores may not be the argmax of the probabilities. Eg in binary classification a sample may be labeled by `predict` as belonging to a class that has probability $\frac{1}{2}$ according to `predict_proba`. Platt's method is also known to have theoretical issues. If confidence scores are required but these do not have to be probabilities then it is advisable to set `probability=False` and use `decisionfunction` instead of `predict_proba`.

Unbalanced problems

In problems where it is desired to give more importance to certain classes or certain individual samples `class_weight` and `sample_weight` can be used. `SVC` (Support Vector Classification) but not `NuSVC` implement a keyword `class_weight` in the `fit` method. It's a dictionary of the form `classlabel: value` where `value` is a floating point number > 0 that sets the parameter `C` of class `classlabel` to `C*value`.

scikitlearn user guide Release 0213

SVCNuSVC SVRNuSVR andOneClassSVM implement also weights for individual samples in method fit through keyword sampleweight Similar to classweight these set the parameter Cfor the ith example to Csampleweighti

Examples

- Plot different SVM (Support Vector Machine) classifiers in the iris dataset
- SVM (Support Vector Machine) Maximum margin separating hyperplane
- SVM (Support Vector Machine) Separating hyperplane for unbalanced classes
- SVMANova SVM (Support Vector Machine) with univariate feature selection
- Nonlinear SVM (Support Vector Machine)
- SVM (Support Vector Machine) Weighted samples

Regression

The method of Support Vector Classification can be extended to solve regression problems This method is called Support Vector Regression

The model produced by support vector classification as described above depends only on a subset of the training data because the cost function for building the model does not care about training points that lie beyond the margin Analogously the model produced by Support Vector Regression depends only on a subset of the training data because the cost function for building the model ignores any training data close to the model prediction

There are three different implementations of Support Vector Regression SVRNuSVR andLinearSVR

LinearSVR provides a faster implementation than SVR (Support Vector Regression) but only considers linear kernels while NuSVR implements a slightly different formulation than SVR (Support Vector Regression) andLinearSVR See Implementation details for further details

As with classification classes the fit method will take as argument vectors X y only that in this case y is expected to have floating point values instead of integer values

```
from sklearn import svm
```

```
X 0 0 2 2
```

Examples

- Support Vector Regression SVR (Support Vector Regression) using linear and nonlinear kernels

Density estimation novelty detection

The classOneClassSVM implements a OneClass SVM (Support Vector Machine) which is used in outlier detection

SeeNovelty and Outlier Detection for the description and usage of OneClassSVM

Complexity

Support Vector Machines are powerful tools but their compute and storage requirements increase rapidly with the number of training vectors The core of an SVM (Support Vector Machine) is a quadratic programming problem QP separating support vectors from the rest of the training data The QP solver used by this libsvmbased implementation scales between

n^2

and n^3

depending on how efficiently the libsvm cache is used in

practice dataset dependent If the data is very sparse n should be replaced by the average number of non zero features in a sample vector

Also note that for the linear case the algorithm used in LinearSVC by the liblinear implementation is much more efficient than its libsvmbased SVC (Support Vector Classification) counterpart and can scale almost linearly to millions of samples and/or features

Tips on Practical Use

- Avoiding data copy ForSVCSVRNuSVC andNuSVR if the data passed to certain methods is not Cordered contiguous and double precision it will be copied before calling the underlying C implementation You can check whether a given numpy array is Ccontiguous by inspecting its flags attribute ForLinearSVC andLogisticRegression any input passed as a numpy array will be copied and converted to the liblinear internal sparse data representation double precision floats and int32 indices of nonzero components If you want to fit a largescale linear classifier without copying a dense numpy Ccontiguous double precision array as input we suggest to use the SGDClassifier class instead The objective function can be configured to be almost the same as the LinearSVC model

- Kernel cache size ForSVCSVRNuSVC andNuSVR the size of the kernel cache has a strong impact on run times for larger problems If you have enough RAM available it is recommended to set cachesize to a higher value than the default of 200MB such as 500MB or 1000MB

- Setting C C is 1 by default and it's a reasonable default choice If you have a lot of noisy observations you should decrease it It corresponds to regularize more the estimation

LinearSVC andLinearSVR are less sensitive to Cwhen it becomes large and prediction results stop improving after a certain threshold Meanwhile larger C values will take more time to train sometimes up to 10 times longer as shown by Fan et al 2008

scikitlearn user guide Release 0213

- Support Vector Machine algorithms are not scale invariant so it is highly recommended to scale your data For example scale each attribute on the input vector X to 01 or 11 or standardize it to have mean 0 and variance 1 Note that the same scaling must be applied to the test vector to obtain meaningful results See section Preprocessing data for more details on scaling and normalization
- Parameter nu in NuSVC OneClassSVM NuSVR approximates the fraction of training errors and support vectors
- In SVC if data for classification are unbalanced eg many positive and few negative set class_weight=balanced and/or try different penalty parameters C
- Randomness of the underlying implementations The underlying implementations of SVC (Support Vector Classification) and NuSVC use a random number generator only to shuffle the data for probability estimation when probability is set to True This randomness can be controlled with the random_state parameter If probability is set to False these estimators are not random and random_state has no effect on the results The underlying OneClassSVM implementation is similar to the ones of SVC (Support Vector Classification) and NuSVC As no probability estimation is provided for OneClassSVM it is not random The underlying LinearSVC implementation uses a random number generator to select features when fitting the model with a dual coordinate descent ie when dual is set to True It is thus not uncommon to have slightly different results for the same input data If that happens try with a smaller tol parameter This randomness can also be controlled with the random_state parameter When dual is set to False the underlying implementation of LinearSVC is not random and random_state has no effect on the results
- Using L1 penalization as provided by LinearSVC loss_l2 penalty_l1 dual=False yields a sparse solution ie only a subset of feature weights is different from zero and contribute to the decision function Increasing C yields a more complex model more features are selected The C value that yields a “null” model all weights equal to zero can be calculated using l1_minc

References

- Fan RongEn et al “LIBLINEAR A library for large linear classification” Journal of machine learning research 9 Aug 2008 1871-1874

Kernel functions

The kernel function can be any of the following

- linear(γ)
- polynomial $\langle \mathbf{x} \cdot \mathbf{x}' \rangle^d$ is specified by keyword degree d by coef0
- rbf $\exp(-\gamma \| \mathbf{x} - \mathbf{x}' \|^2)$ is specified by keyword gamma must be greater than 0
- sigmoid $\tanh(\gamma \langle \mathbf{x} \cdot \mathbf{x}' \rangle)$ where γ is specified by coef0

Different kernels are specified by keyword kernel at initialization

```
linearsvc svmSVCKernel(linear)
linearsvc Kernel
linear
rbfsvc svmSVCKernel(rbf)
rbfsvc Kernel
rbf
```

Custom Kernels

You can define your own kernels by either giving the kernel as a python function or by precomputing the Gram matrix
Classifiers with custom kernels behave the same way as any other classifiers except that

- Fieldsupportvectors is now empty only indices of support vectors are stored in support
- A reference and not a copy of the first argument in the fit method is stored for future reference If that array changes between the use of fit andpredict you will have unexpected results

Using Python functions as kernels

You can also use your own defined kernels by passing a function to the keyword kernel in the constructor

Your kernel must take as arguments two matrices of shape nsamples1 nfeatures nsamples2
nfeatures and return a kernel matrix of shape nsamples1 nsamples2

The following code defines a linear kernel and creates a classifier instance that will use that kernel

```
import numpy as np
from sklearn import svm
def mykernel(X, Y):
    return np.dot(X, Y.T)

clf = svm.SVC(kernel=mykernel)
```

Examples

- SVM (Support Vector Machine) with custom kernel

Using the Gram matrix

Setkernelprecomputed and pass the Gram matrix instead of X in the fit method At the moment the kernel values between alltraining vectors and the test vectors must be provided

```
import numpy as np
from sklearn import svm
X = np.array([0, 0, 1, 1])
y = [0, 1]
clf = svm.SVC(kernel=precomputed)
# linear kernel computation
gram = np.dot(X, X.T)
clf.fit(gram, y)
SVCC10 cachesize200 classweightNone coef000
decisionfunctionshapeovr degree3 gammaautodeprecated
kernelprecomputed maxiter1 probabilityFalse
randomstateNone shrinkingTrue tol0001 verboseFalse
# predict on training examples
clf.predict(gram)
array([0, 1])
```

scikitlearn user guide Release 0213

Parameters of the RBF (Radial Basis Function) Kernel

When training an SVM (Support Vector Machine) with the Radial Basis Function RBF (Radial Basis Function) kernel two parameters must be considered: C and γ . The parameter C common to all SVM (Support Vector Machine) kernels trades off misclassification of training examples against simplicity of the decision surface. A low C makes the decision surface smooth while a high C aims at classifying all training examples correctly. γ defines how much influence a single training example has. The larger γ is, the closer other examples must be to be affected.

Proper choice of C and γ is critical to the SVM (Support Vector Machine)'s performance. One is advised to use `sklearn.model_selection.GridSearchCV` with C and γ spaced exponentially far apart to choose good values.

Examples

- RBF (Radial Basis Function) SVM (Support Vector Machine) parameters

Mathematical formulation

A support vector machine constructs a hyperplane or set of hyperplanes in a high or infinite dimensional space which can be used for classification, regression or other tasks. Intuitively, a good separation is achieved by the hyperplane that has the largest distance to the nearest training data points of any class, so-called functional margin. Since in general the larger the margin the lower the generalization error of the classifier.

234 Chapter 3 User Guide

SVC (Support Vector Classification)

Given training vectors $x_i \in \mathbb{R}^n$ in two classes and a vector $\gamma \in [1, -1]$ SVC (Support Vector Classification) solves the following primal problem

$$\begin{aligned} \min \quad & \frac{1}{2} \sum_{i=1}^n \xi_i \\ \text{subject to} \quad & \gamma x_i^T w + b \geq 1 - \xi_i \\ & \xi_i \geq 0 \quad \forall i \end{aligned}$$

Its dual is

$$\begin{aligned} \min \quad & \frac{1}{2} \sum_{i=1}^n \alpha_i^2 \\ \text{subject to} \quad & \alpha_i \geq 0 \\ & 0 \leq \alpha_i \leq \gamma_i \quad \forall i \end{aligned}$$

where γ is the vector of all ones, γ_i is the upper bound, α is an n -by- n positive semidefinite matrix $\alpha_{ij} = \gamma_i \gamma_j K(x_i, x_j)$ where $K(x_i, x_j)$ is the kernel. Here training vectors are implicitly mapped into a higher maybe infinite dimensional space by the function ϕ .

The decision function is

$$\text{sgn} \left(\sum_{i=1}^n \alpha_i \gamma_i \phi(x_i)^T \phi(x) + b \right)$$

Note While SVM (Support Vector Machine) models derived from libsvm and liblinear use C as regularization parameter most other estimators use α . The exact equivalence between the amount of regularization of two models depends on the exact objective function optimized by the model. For example when the estimator used is `sklearn.linear_model.RidgeRegression` the relation between them is given as $\alpha = 1/C$.

This parameters can be accessed through the members `dual_coef` which holds the product $\sum \alpha_i \gamma_i \phi(x_i)$, `support_vectors` which holds the support vectors and `intercept` which holds the independent term b .

NuSVC

We introduce a new parameter ν which controls the number of support vectors and training errors. The parameter $\nu \in [0, 1]$ is an upper bound on the fraction of training errors and a lower bound of the fraction of support vectors. It can be shown that the ν -SVC formulation is a reparameterization of the C -SVC and therefore mathematically equivalent.

SVR (Support Vector Regression)

Given training vectors $x_i \in \mathbb{R}^n$ and a vector $y \in \mathbb{R}$ SVR solves the following primal problem

$$\begin{aligned} \min_{\alpha, \xi} \quad & \frac{1}{2} \sum_{i=1}^n \xi_i^2 \\ \text{subject to} \quad & y_i - \sum_{j=1}^n \alpha_j x_{ij} - \xi_i \leq 0 \\ & \xi_i \geq 0 \end{aligned}$$

Its dual is

$$\begin{aligned} \min_{\alpha} \quad & \frac{1}{2} \sum_{i=1}^n \xi_i^2 \\ \text{subject to} \quad & 0 \leq \alpha_i \leq 1 \end{aligned}$$

where $\mathbf{1}$ is the vector of all ones ξ is the upper bound \mathbf{K} is an $n \times n$ positive semidefinite matrix $\mathbf{K}_{ij} = \kappa(x_i, x_j)$ is the kernel Here training vectors are implicitly mapped into a higher maybe infinite dimensional space by the function ϕ

The decision function is

$$\hat{y} = \sum_{i=1}^n \alpha_i (y_i - \xi_i) + \xi_0$$

These parameters can be accessed through the members `dualcoef` which holds the difference $y_i - \xi_i$ `supportvectors` which holds the support vectors and `intercept` which holds the independent term ξ_0

315 Stochastic Gradient Descent

Stochastic Gradient Descent SGD is a simple yet very efficient approach to discriminative learning of linear classifiers under convex loss functions such as linear Support Vector Machines and Logistic Regression Even though

scikitlearn user guide Release 0213

SGD has been around in the machine learning community for a long time it has received a considerable amount of attention just recently in the context of largescale learning
SGD has been successfully applied to largescale and sparse machine learning problems often encountered in text classification and natural language processing Given that the data is sparse the classifiers in this module easily scale to problems with more than 105 training examples and more than 105 features

The advantages of Stochastic Gradient Descent are

- Efficiency
- Ease of implementation lots of opportunities for code tuning

The disadvantages of Stochastic Gradient Descent include

- SGD requires a number of hyperparameters such as the regularization parameter and the number of iterations
- SGD is sensitive to feature scaling

Classification

Warning Make sure you permute shuffle your training data before fitting the model or use shuffleTrue

to shuffle after each iteration

The classSGDClassifier implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties for classification

As other classifiers SGD has to be fitted with two arrays an array X of size nsamples nfeatures holding the training samples and an array Y of size nsamples holding the target values class labels for the training samples

from sklearnlinearmodel import SGDClassifier

X 0 0 1 1

31 Supervised learning 237

scikitlearn user guide Release 0213

```
y 0 1
clf = SGDClassifier(loss=shinge, penalty=l2, max_iter=5
clf.fit(X, y)
SGDClassifier(alpha=0.0001, average=False, class_weight=None
early_stopping=False, epsilon=0.1, eta=0.00, fit_intercept=True
l1_ratio=0.15, learning_rate=optimal, loss=shinge, max_iter=5
n_iter_no_change=5, n_jobs=None, penalty=l2, power_t=0.5
random_state=None, shuffle=True, tol=0.0001
validation_fraction=0.1, verbose=0, warm_start=False
After being fitted the model can then be used to predict new values
clf.predict(2, 2)
array(1)
```

SGD fits a linear model to the training data. The member coef holds the model parameters

```
clf.coef
array(99, 99)
Member.intercept holds the intercept aka offset or bias
clf.intercept
array(99)
```

Whether or not the model should use an intercept ie a biased hyperplane is controlled by the parameter fit_intercept

To get the signed distance to the hyperplane use SGDClassifier.decision_function

```
clf.decision_function(2, 2)
array(296)
The concrete loss function can be set via the loss parameter. SGDClassifier supports the following loss functions
```

- loss=shinge: softmargin linear Support Vector Machine
- loss=modifiedhuber: smoothed hinge loss
- loss=log: logistic regression
- and all regression losses below

The first two loss functions are lazy: they only update the model parameters if an example violates the margin constraint which makes training very efficient and may result in sparser models even when L2 penalty is used. Using loss=log or loss=modifiedhuber enables the predict_proba method which gives a vector

```
of probability estimates (per sample)
clf = SGDClassifier(loss=log, max_iter=5)
clf.fit(X, y)
clf.predict_proba(1, 1)
array(0.00, 0.99)
```

The concrete penalty can be set via the penalty parameter. SGD supports the following penalties

- penalty=l2: L2 norm penalty on coef
- penalty=l1: L1 norm penalty on coef

- penaltyelasticnet Convex combination of L2 and L1 1 l1ratio L2 l1ratio L1

The default setting is penaltyl2 The L1 penalty leads to sparse solutions driving most coefficients to zero The Elastic Net solves some deficiencies of the L1 penalty in the presence of highly correlated attributes The parameterl1ratio controls the convex combination of L1 and L2 penalty

SGDClassifier supports multiclass classification by combining multiple binary classifiers in a “one versus all” OV A scheme For each of the K classes a binary classifier is learned that discriminates between that and all other $K-1$ classes At testing time we compute the confidence score ie the signed distances to the hyperplane for each classifier and choose the class with the highest confidence The Figure below illustrates the OV A approach on the iris dataset The dashed lines represent the three OV A classifiers the background colors show the decision surface induced by the three classifiers

In the case of multiclass classification coef is a twodimensional array of shapenclasses nfeatures andintercept is a onedimensional array of shapenclasses The ith row of coef holds the weight vector of the OV A classifier for the ith class classes are indexed in ascending order see at tributeclasses Note that in principle since they allow to create a probability model losslog and lossmodifiedhuber are more suitable for onevsall classification SGDClassifier supports both weighted classes and weighted instances via the fit parameters classweight andsampleweight See the examples below and the docstring of SGDClassifierfit for further information

Examples

- SGD Maximum margin separating hyperplane
 - Plot multiclass SGD on the iris dataset
 - SGD Weighted samples
 - Comparing various online solvers

scikitlearn user guide Release 0213

•SVM (Support Vector Machine) Separating hyperplane for unbalanced classes See theNote

SGDClassifier supports averaged SGD ASGD Averaging can be enabled by setting averageTrue

ASGD works by averaging the coefficients of the plain SGD over each iteration over a sample When using ASGD

the learning rate can be larger and even constant leading on some datasets to a speed up in training time

For classification with a logistic loss another variant of SGD with an averaging strategy is available with Stochastic

Average Gradient SAG algorithm available as a solver in LogisticRegression

Regression

The classSGDRegressor implements a plain stochastic gradient descent learning routine which supports different

loss functions and penalties to fit linear regression models SGDRegressor is well suited for regression prob

lems with a large number of training samples 10000 for other problems we recommend Ridge Lasso or

ElasticNet

The concrete loss function can be set via the loss parameterSGDRegressor supports the following loss functions

•losssquaredloss Ordinary least squares

•losshuber Huber loss for robust regression

•lossepsiloninsensitive linear Support Vector Regression

The Huber and epsiloninsensitive loss functions can be used for robust regression The width of the insensitive region

has to be specified via the parameter epsilon This parameter depends on the scale of the target variables

SGDRegressor supports averaged SGD as SGDClassifier Averaging can be enabled by setting

averageTrue

For regression with a squared loss and a l2 penalty another variant of SGD with an averaging strategy is available with

Stochastic Average Gradient SAG algorithm available as a solver in Ridge

Stochastic Gradient Descent for sparse data

Note The sparse implementation produces slightly different results than the dense implementation due to a shrunk

learning rate for the intercept

There is builtin support for sparse data given in any matrix in a format supported by scipysparse For maximum

efficiency however use the CSR (Compressed Sparse Row) matrix format as defined in scipysparsecsrmatrix

Examples

•Classification of text documents using sparse features

Complexity

The major advantage of SGD is its efficiency which is basically linear in the number of training examples If X is a

matrix of size n p training has a cost of kp where k is the number of iterations epochs and p is the average

number of nonzero attributes per sample

Recent theoretical results however show that the runtime to get some desired optimization accuracy does not increase

as the training set size increases

240 Chapter 3 User Guide

Stopping criterion

The classes SGDClassifier andSGDRegressor provide two criteria to stop the algorithm when a given level of convergence is reached

- WithearlystoppingTrue the input data is split into a training set and a validation set The model is then fitted on the training set and the stopping criterion is based on the prediction score computed on the validation set The size of the validation set can be changed with the parameter validationfraction
- WithearlystoppingFalse the model is fitted on the entire input data and the stopping criterion is based on the objective function computed on the input data

In both cases the criterion is evaluated once by epoch and the algorithm stops when the criterion does not improve niternochange times in a row The improvement is evaluated with a tolerance tol and the algorithm stops in any case after a maximum number of iteration maxiter

Tips on Practical Use

- Stochastic Gradient Descent is sensitive to feature scaling so it is highly recommended to scale your data For example scale each attribute on the input vector X to 01 or 11 or standardize it to have mean 0 and variance 1 Note that the same scaling must be applied to the test vector to obtain meaningful results This can be easily done using StandardScaler

from sklearnpreprocessing import StandardScaler
scaler = StandardScaler

scaler.fit(Xtrain) Dont cheat fit only on training data

Xtrain = scaler.transform(Xtrain)

Xtest = scaler.transform(Xtest) apply same transformation to test data

If your attributes have an intrinsic scale eg word frequencies or indicator features scaling is not needed

- Finding a reasonable regularization term λ is best done using GridSearchCV usually in the range 10^{-5} to 10^{-1}

- Empirically we found that SGD converges after observing approx 10^6 training samples Thus a reasonable first guess for the number of iterations is $\max(\maxiter, \lceil 10^6 / n \rceil)$ where n is the size of the training set

- If you apply SGD to features extracted using PCA (Principal Component Analysis) we found that it is often wise to scale the feature values by some constant c such that the average L2 norm of the training data equals one

- We found that Averaged SGD works best with a larger number of features and a higher η

Mathematical formulation

Given a set of training examples $\{(x_i, y_i)\}_{i=1}^n$ where $x_i \in \mathbb{R}^d$ and $y_i \in \{-1, 1\}$ our goal is to learn a linear scoring function $f(x) = w^T x + b$ with model parameters $w \in \mathbb{R}^d$ and intercept $b \in \mathbb{R}$. In order to make predictions we simply look at the sign of $f(x)$. A common choice to find the model parameters is by minimizing the regularized training error given by

$$J(w, b) = \frac{1}{n} \sum_{i=1}^n \max(0, 1 - y_i (w^T x_i + b)) + \frac{\lambda}{2} \|w\|^2$$

where ℓ is a loss function that measures model misfit and λ is a regularization term aka penalty that penalizes model complexity. $\lambda \geq 0$ is a nonnegative hyperparameter.

Different choices for ℓ entail different classifiers such as

- Hinge softmargin Support Vector Machines
- Log Logistic Regression
- LeastSquares Ridge Regression
- EpsilonInsensitive softmargin Support Vector Regression

All of the above loss functions can be regarded as an upper bound on the misclassification error. Zero-one loss as shown in the Figure below.

Popular choices for the regularization term λ include

- L2 norm $\lambda \sum_i w_i^2$

$\lambda \sum_i |w_i|$

- L1 norm $\lambda \sum_i |w_i|$

$\lambda \sum_i |w_i|$ which leads to sparse solutions

- Elastic Net $\lambda (\alpha \sum_i |w_i| + (1-\alpha) \sum_i w_i^2)$

$\lambda \sum_i |w_i|$

$\lambda \sum_i w_i^2$

$\lambda \sum_i |w_i|$

$\lambda \sum_i |w_i|$

$\lambda \sum_i |w_i|$ a convex combination of L2 and L1 where α is given

by $\alpha = \frac{\lambda_1}{\lambda_1 + \lambda_2}$

The Figure below shows the contours of the different regularization terms in the parameter space when $\lambda \geq 0$.

SGD

Stochastic gradient descent is an optimization method for unconstrained optimization problems. In contrast to batch

gradient descent, SGD approximates the true gradient of $J(w)$ by considering a single training example at a time.

The class `SGDClassifier` implements a first-order SGD learning routine. The algorithm iterates over the training

examples and for each example updates the model parameters according to the update rule given by

$$\theta \leftarrow \theta - \eta \nabla_{\theta} L(\theta; x, y)$$

where η is the learning rate which controls the stepsize in the parameter space The intercept θ_0 is updated similarly but without regularization

The learning rate η can be either constant or gradually decaying For classification the default learning rate schedule `learningrateoptimal` is given by

$$\eta = \frac{1}{\sqrt{n \cdot t}}$$

where t is the time step there are a total of `nsamples` niter time steps η is determined based on a heuristic proposed by Léon Bottou such that the expected initial updates are comparable with the expected size of the weights this assuming that the norm of the training samples is approx 1 The exact definition can be found in `initt` in `BaseSGD`

For regression the default learning rate schedule is inverse scaling `learningrateinvscaling` given by

$$\eta = \frac{\eta_0}{1 + \text{power} \cdot t}$$

where η_0 and `power` are hyperparameters chosen by the user via `eta0` and `power` resp

For a constant learning rate use `learningrateconstant` and `useeta0` to specify the learning rate

For an adaptively decreasing learning rate use `learningrateadaptive` and `useeta0` to specify the start

ing learning rate When the stopping criterion is reached the learning rate is divided by 5 and the algorithm does not stop The algorithm stops when the learning rate goes below `1e6`

The model parameters can be accessed through the members `coef` and `intercept`

- `Membercoef` holds the weights θ
- `Memberintercept` holds θ_0

Implementation details

The implementation of SGD is influenced by the Stochastic Gradient SVM (Support Vector Machine) of Léon Bottou Similar to `SvmSGD` the weight vector is represented as the product of a scalar and a vector which allows an efficient weight update in the case of L2 regularization In the case of sparse feature vectors the intercept is updated with a smaller learning rate multiplied by 0.01 to account for the fact that it is updated more frequently Training examples are picked up sequentially and the learning rate is lowered after each observed example We adopted the learning rate schedule from ShalevShwartz et al 2007 For multiclass classification a “one versus all” approach is used We use the truncated gradient algorithm proposed by Tsuruoka et al 2009 for L1 regularization and the Elastic Net The code is written in Cython

316 Nearest Neighbors

sklearnneighbors provides functionality for unsupervised and supervised neighborsbased learning methods

Unsupervised nearest neighbors is the foundation of many other learning methods notably manifold learning and spectral clustering Supervised neighborsbased learning comes in two flavors classification for data with discrete labels and regression for data with continuous labels

The principle behind nearest neighbor methods is to find a predefined number of training samples closest in distance to the new point and predict the label from these The number of samples can be a userdefined constant knearest neighbor learning or vary based on the local density of points radiusbased neighbor learning The distance can in general be any metric measure standard Euclidean distance is the most common choice Neighborsbased methods are known as nongeneralizing machine learning methods since they simply “remember” all of its training data possibly transformed into a fast indexing structure such as a Ball Tree orKD Tree

Despite its simplicity nearest neighbors has been successful in a large number of classification and regression problems including handwritten digits and satellite image scenes Being a nonparametric method it is often successful in classification situations where the decision boundary is very irregular

The classes in sklearnneighbors can handle either NumPy arrays or scipysparse matrices as input For dense matrices a large number of possible distance metrics are supported For sparse matrices arbitrary Minkowski metrics are supported for searches

There are many learning routines which rely on nearest neighbors at their core One example is kernel density estimation discussed in the density estimation section

Unsupervised Nearest Neighbors

NearestNeighbors implements unsupervised nearest neighbors learning It acts as a uniform interface to three different nearest neighbors algorithms BallTree KDTree and a brute force algorithm based on routines in sklearnmetricspairwise The choice of neighbors search algorithm is controlled through the keyword algorithm which must be one of auto balltree kdtree brute When the default value auto is passed the algorithm attempts to determine the best approach from the training data For a discussion of the strengths and weaknesses of each option see Nearest Neighbor Algorithms

Warning Regarding the Nearest Neighbors algorithms if two neighbors x_1 and x_2 have identical distances but different labels the result will depend on the ordering of the training data

31 Supervised learning 245

Finding the Nearest Neighbors

For the simple task of finding the nearest neighbors between two sets of data the unsupervised algorithms within sklearnneighbors can be used

```
from sklearnneighbors import NearestNeighbors
import numpy as np
X nparray1 1 2 1 3 2 1 1 2 1 3 2
nbrs NearestNeighborsnneighbors2 algorithmballtreefitX
distances indices nbrskneighborsX
```

```
indices
array0 1
1 0
2 1
3 4
4 3
5 4
distances
array0 1
0 1
0 141421356
0 1
0 1
0 141421356
```

Because the query set matches the training set the nearest neighbor of each point is the point itself at a distance of zero

It is also possible to efficiently produce a sparse graph showing the connections between neighboring points

```
nbrskneighborsgraphXtoarray
array1 1 0 0 0 0
1 1 0 0 0 0
0 1 1 0 0 0
0 0 0 1 1 0
0 0 0 1 1 0
0 0 0 0 1 1
```

The dataset is structured such that points nearby in index order are nearby in parameter space leading to an approximately blockdiagonal matrix of Knearest neighbors Such a sparse graph is useful in a variety of circumstances which make use of spatial relationships between points for unsupervised learning in particular seeksklearnmanifoldIsomap sklearnmanifoldLocallyLinearEmbedding andsklearn

clusterSpectralClustering
KDTree and BallTree Classes

Alternatively one can use the KDTree orBallTree classes directly to find nearest neighbors This is the functionality wrapped by the NearestNeighbors class used above The Ball Tree and KD Tree have the same interface we'll show an example of using the KD Tree here

```
from sklearnneighbors import KDTree
import numpy as np
X nparray1 1 2 1 3 2 1 1 2 1 3 2
kdt KDTreeX leafsize30 metric=euclidean
kdtqueryX k2 returndistance=False
array0 1
```

Refer to the KDTree andBallTree class documentation for more information on the options available for nearest neighbors searches including specification of query strategies distance metrics etc For a list of available metrics see the documentation of the DistanceMetric class

Nearest Neighbors Classification

Neighborsbased classification is a type of instancebased learning ornongeneralizing learning it does not attempt to construct a general internal model but simply stores instances of the training data Classification is computed from a simple majority vote of the nearest neighbors of each point a query point is assigned the data class which has the most representatives within the nearest neighbors of the point

scikitlearn implements two different nearest neighbors classifiers KNeighborsClassifier implements learning based on the k nearest neighbors of each query point where k is an integer value specified by the user

RadiusNeighborsClassifier implements learning based on the number of neighbors within a fixed radius ϵ of each training point where ϵ is a floatingpoint value specified by the user

The k neighbors classification in KNeighborsClassifier is the most commonly used technique The optimal choice of the value k is highly datadependent in general a larger k suppresses the effects of noise but makes the classification boundaries less distinct

In cases where the data is not uniformly sampled radiusbased neighbors classification in

RadiusNeighborsClassifier can be a better choice The user specifies a fixed radius ϵ such that

points in sparser neighborhoods use fewer nearest neighbors for the classification For highdimensional parameter spaces this method becomes less effective due to the socalled “curse of dimensionality”

The basic nearest neighbors classification uses uniform weights that is the value assigned to a query point is computed from a simple majority vote of the nearest neighbors Under some circumstances it is better to weight the neighbors such that nearer neighbors contribute more to the fit This can be accomplished through the weights keyword The default value weights uniform assigns uniform weights to each neighbor weights distance assigns weights proportional to the inverse of the distance from the query point Alternatively a userdefined function of the distance can be supplied to compute the weights

Examples

•Nearest Neighbors Classification an example of classification using nearest neighbors

Nearest Neighbors Regression

Neighborsbased regression can be used in cases where the data labels are continuous rather than discrete variables

The label assigned to a query point is computed based on the mean of the labels of its nearest neighbors

scikitlearn implements two different neighbors regressors KNeighborsRegressor implements learning

based on the k nearest neighbors of each query point where k is an integer value specified by the user

RadiusNeighborsRegressor implements learning based on the neighbors within a fixed radius ϵ of the query

point where ϵ is a floatingpoint value specified by the user

The basic nearest neighbors regression uses uniform weights that is each point in the local neighborhood contributes

uniformly to the classification of a query point Under some circumstances it can be advantageous to weight points

such that nearby points contribute more to the regression than faraway points This can be accomplished through the

weights keyword The default value weights uniform assigns equal weights to all points weights

distance assigns weights proportional to the inverse of the distance from the query point Alternatively a

userdefined function of the distance can be supplied which will be used to compute the weights

The use of multioutput nearest neighbors for regression is demonstrated in Face completion with a multioutput

estimators In this example the inputs X are the pixels of the upper half of faces and the outputs Y are the pixels of

the lower half of those faces

Examples

•Nearest Neighbors regression an example of regression using nearest neighbors

•Face completion with a multioutput estimators an example of multioutput regression using nearest neighbors

Nearest Neighbor Algorithms

Brute Force

Fast computation of nearest neighbors is an active area of research in machine learning The most naive neighbor search implementation involves the brute force computation of distances between all pairs of points in the dataset for n samples in d dimensions this approach scales as $O(n^2d)$ Efficient brute force neighbors searches can be very competitive for small data samples However as the number of samples n grows the brute force approach quickly becomes infeasible In the classes within `sklearn.neighbors` brute force neighbors searches are specified using the keyword algorithm `brute` and are computed using the routines available in `sklearn.metrics`

pairwise

KD Tree

To address the computational inefficiencies of the brute force approach a variety of tree based data structures have been invented In general these structures attempt to reduce the required number of distance calculations by efficiently encoding aggregate distance information for the sample The basic idea is that if point p is very distant from point q and point r is very close to point q then we know that points p and r are very distant without having to explicitly calculate their distance In this way the computational cost of a nearest neighbors search can be reduced to $O(n \log n)$ or better This is a significant improvement over brute force for large n

An early approach to taking advantage of this aggregate information was the KD tree data structure short for K dimensional tree which generalizes two dimensional Quad trees and 3 dimensional Oct trees to an arbitrary number of dimensions The KD tree is a binary tree structure which recursively partitions the parameter space along the data axes dividing it into nested orthotropic regions into which data points are filed The construction of a KD tree is very fast because partitioning is performed only along the data axes no d dimensional distances need to be computed Once constructed the nearest neighbor of a query point can be determined with only $O(\log n)$ distance computations Though the KD tree approach is very fast for low dimensional $d \leq 20$ neighbors searches it becomes inefficient as n grows very large this is one manifestation of the so called “curse of dimensionality” In scikitlearn KD tree neighbors searches are specified using the keyword algorithm `kdtree` and are computed using the class

KDTree

References

- “Multidimensional binary search trees used for associative searching” Bentley JL Communications of the ACM 1975

Ball Tree

To address the inefficiencies of KD Trees in higher dimensions the ball tree data structure was developed Where KD trees partition data along Cartesian axes ball trees partition data in a series of nesting hyperspheres This makes tree construction more costly than that of the KD tree but results in a data structure which can be very efficient on highly structured data even in very high dimensions

A ball tree recursively divides the data into nodes defined by a centroid c and radius r such that each point in the node lies within the hypersphere defined by c and r The number of candidate points for a neighbor search is reduced

scikitlearn user guide Release 0213
through use of the triangle inequality
 $d(x, c) \leq d(x, y) + d(y, c)$

With this setup a single distance calculation between a test point and the centroid is sufficient to determine a lower and upper bound on the distance to all points within the node Because of the spherical geometry of the ball tree nodes it can outperform a KDtree in high dimensions though the actual performance is highly dependent on the structure of the training data In scikitlearn balltreebased neighbors searches are specified using the keyword algorithm 'balltree' and are computed using the class sklearn.neighbors.BallTree Alternatively the user can work with the BallTree class directly

References
• "Five balltree construction algorithms" Omohundro SM International Computer Science Institute Technical Report 1989

Choice of Nearest Neighbors Algorithm

The optimal algorithm for a given dataset is a complicated choice and depends on a number of factors

- number of samples n and dimensionality d

-Brute force query time grows as n^2

-Ball tree query time grows as approximately $n \log n$

-KD tree query time changes with d in a way that is difficult to precisely characterise For small d less than 20 or so the cost is approximately $n \log n$ and the KD tree query can be very efficient For larger d the cost increases to nearly n^2 and the overhead due to the tree structure can lead to queries which are slower than brute force

For small data sets d less than 30 or so $\log d$ is comparable to d and brute force algorithms can be more efficient than a treebased approach Both KDTree and BallTree address this through providing a leaf size parameter this controls the number of samples at which a query switches to brute force This allows both algorithms to approach the efficiency of a brute force computation for small d

- data structure intrinsic dimensionality of the data and/or sparsity of the data Intrinsic dimensionality refers to the dimension $k \leq d$ of a manifold on which the data lies which can be linearly or nonlinearly embedded in the parameter space Sparsity refers to the degree to which the data fills the parameter space this is to be distinguished from the concept as used in "sparse" matrices The data matrix may have no zero entries but the structure can still be "sparse" in this sense

-Brute force query time is unchanged by data structure

-Ball tree and KD tree query times can be greatly influenced by data structure In general sparser data with a smaller intrinsic dimensionality leads to faster query times Because the KD tree internal representation is aligned with the parameter axes it will not generally show as much improvement as ball tree for arbitrarily structured data

Datasets used in machine learning tend to be very structured and are very well suited for treebased queries

- number of neighbors k requested for a query point

-Brute force query time is largely unaffected by the value of k

-Ball tree and KD tree query time will become slower as k increases This is due to two effects first a larger k leads to the necessity to search a larger portion of the parameter space Second using $k = 1$ requires internal queueing of results as the tree is traversed

As n becomes large compared to k the ability to prune branches in a treebased query is reduced In this situation Brute force queries can be more efficient

- number of query points Both the ball tree and the KD Tree require a construction phase The cost of this construction becomes negligible when amortized over many queries If only a small number of queries will be performed however the construction can make up a significant fraction of the total cost If very few query points will be required brute force is better than a treebased method

Currently algorithm `auto` selects `brute` if $n \leq 2$ the input data is sparse or `effectivemetric` isn't in the `VALIDMETRICS` list for either `kdtree` or `balltree` Otherwise it selects the first out of `kdtree` and `balltree` that has `effectivemetric` in its `VALIDMETRICS` list This choice is based on the assumption that the number of query points is at least the same order as the number of training points and that `leafsize` is close to its default value of 30

Effect of `leafsize`

As noted above for small sample sizes a brute force search can be more efficient than a treebased query This fact is accounted for in the ball tree and KD tree by internally switching to brute force searches within leaf nodes The level of this switch can be specified with the parameter `leafsize` This parameter choice has many effects

construction time A larger `leafsize` leads to a faster tree construction time because fewer nodes need to be created

query time Both a large or small `leafsize` can lead to suboptimal query cost For `leafsize` approaching 1 the overhead involved in traversing nodes can significantly slow query times For `leafsize` approaching the size of the training set queries become essentially brute force A good compromise between these is `leafsize = 30` the default value of the parameter

memory As `leafsize` increases the memory required to store a tree structure decreases This is especially important in the case of ball tree which stores a k -dimensional centroid for each node The required storage space for `BallTree` is approximately $1 / \text{leafsize}$ times the size of the training set

`leafsize` is not referenced for brute force queries

Nearest Centroid Classifier

The `NearestCentroid` classifier is a simple algorithm that represents each class by the centroid of its members In effect this makes it similar to the label updating phase of the `sklearnKMeans` algorithm It also has no parameters to choose making it a good baseline classifier It does however suffer on nonconvex classes as well as when classes have drastically different variances as equal variance in all dimensions is assumed See `Linear Discriminant Analysis` `sklearn discriminant analysis LinearDiscriminantAnalysis` and `Quadratic Discriminant Analysis` `sklearn discriminant analysis QuadraticDiscriminantAnalysis` for more complex methods that do not make this assumption Usage of the default `NearestCentroid` is simple

```
from sklearn.neighbors.nearestcentroid import NearestCentroid
import numpy as np
X = np.array([1 2 1 3 2 1 1 2 1 3 2])
y = np.array([1 1 1 2 2 2])
clf = NearestCentroid
clf.fit(X, y)
NearestCentroid(metric=euclidean shrinkthreshold=None)
print(clf.predict([0.8, 1.1]))
```

Nearest Shrunk Centroid

TheNearestCentroid classifier has a shrinkthreshold parameter which implements the nearest shrunken centroid classifier In effect the value of each feature for each centroid is divided by the withinclass variance of that feature The feature values are then reduced by shrinkthreshold Most notably if a particular feature value crosses zero it is set to zero In effect this removes the feature from affecting the classification This is useful for example for removing noisy features

In the example below using a small shrink threshold increases the accuracy of the model from 081 to 082

Examples

- Nearest Centroid Classification an example of classification using nearest centroid with different shrink thresholds

Neighborhood Components Analysis

Neighborhood Components Analysis NCA NeighborhoodComponentsAnalysis is a distance metric learning algorithm which aims to improve the accuracy of nearest neighbors classification compared to the standard Euclidean distance The algorithm directly maximizes a stochastic variant of the leaveoneout knearest neighbors KNN score on the training set It can also learn a lowdimensional linear projection of data that can be used for data visualization and fast classification

In the above illustrating figure we consider some points from a randomly generated dataset We focus on the stochastic KNN classification of point no 3 The thickness of a link between sample 3 and another point is proportional to their distance and can be seen as the relative weight or probability that a stochastic nearest neighbor prediction rule would assign to this point In the original space sample 3 has many stochastic neighbors from various classes so the right class is not very likely However in the projected space learned by NCA the only stochastic neighbors with non negligible weight are from the same class as sample 3 guaranteeing that the latter will be well classified See the mathematical formulation for more details

Classification

Combined with a nearest neighbors classifier KNeighborsClassifier NCA is attractive for classification because it can naturally handle multiclass problems without any increase in the model size and does not introduce additional parameters that require finetuning by the user

NCA classification has been shown to work well in practice for data sets of varying size and difficulty In contrast to related methods such as Linear Discriminant Analysis NCA does not make any assumptions about the class distributions The nearest neighbor classification can naturally produce highly irregular decision boundaries

To use this model for classification one needs to combine a NeighborhoodComponentsAnalysis instance that learns the optimal transformation with a KNeighborsClassifier instance that performs the classification in the projected space Here is an example using the two classes

```
from sklearn.neighbors import NeighborhoodComponentsAnalysis
KNeighborsClassifier
from sklearn.datasets import loadiris
from sklearn.model_selection import train_test_split
from sklearn.pipeline import Pipeline
X, y = loadiris(return_Xy=True)
X_train, X_test, y_train, y_test = train_test_split(X, y,
                                                    stratify=y, test_size=0.7, random_state=42)
nca = NeighborhoodComponentsAnalysis(random_state=42)
knn = KNeighborsClassifier(n_neighbors=3)
ncapipeline = Pipeline([
    ('nca', nca),
    ('knn', knn)
])
ncapipeline.fit(X_train, y_train)
print(ncapipeline.score(X_test, y_test))
0.96190476
```

The plot shows decision boundaries for Nearest Neighbor Classification and Neighborhood Components Analysis classification on the iris dataset when training and scoring on only two features for visualisation purposes

Dimensionality reduction

NCA can be used to perform supervised dimensionality reduction The input data are projected onto a linear sub space consisting of the directions which minimize the NCA objective The desired dimensionality can be set using the parameter ncomponents For instance the following figure shows a comparison of dimensionality reduction with Principal Component Analysis sklearn.decomposition.PCA Linear Discriminant Analysis sklearn.discriminantanalysis.LinearDiscriminantAnalysis and Neighborhood Component Analysis NeighborhoodComponentsAnalysis on the Digits dataset a dataset with size 1797 and 64 The data set is split into a training and a test set of equal size then standardized For evaluation the 3nearest neighbor classification accuracy is computed on the 2dimensional projected points found by each method Each data sample belongs to one of 10 classes

Examples

- Comparing Nearest Neighbors with and without Neighborhood Components Analysis
- Dimensionality Reduction with Neighborhood Components Analysis
- Manifold learning on handwritten digits Locally Linear Embedding Isomap

Mathematical formulation

The goal of NCA is to learn an optimal linear transformation matrix of size ncomponents nfeatures which maximises the sum over all samples of the probability that is correctly classified ie

$$\arg \max_{W} -1 \sum_{i=0}^{n-1} \log p_i$$

with n samples and p_i the probability of sample i being correctly classified according to a stochastic nearest neighbors rule in the learned embedded space

$$p_i = \frac{\exp(-\min_{j \in C_i} \|x_i - x_j\|^2)}{\sum_{j \in C_i} \exp(-\|x_i - x_j\|^2)}$$

where C_i is the set of points in the same class as sample i and σ_j is the softmax over Euclidean distances in the embedded space

scikitlearn user guide Release 0213

Mahalanobis distance

NCA can be seen as learning a squared Mahalanobis distance metric

$$\|x - x'\|_M^2 = (x - x')^T M (x - x')$$

where M is a symmetric positive semidefinite matrix of size $n_{\text{features}} \times n_{\text{features}}$

Implementation

This implementation follows what is explained in the original paper¹ For the optimisation method it currently uses

scipy's LBFGSB with a full gradient computation at each iteration to avoid to tune the learning rate and provide

stable learning

See the examples below and the docstring of `NeighborhoodComponentsAnalysis` for further information

Complexity

Training

NCA stores a matrix of pairwise distances taking n_{samples}^2 memory Time complexity depends on the number of iterations done by the optimisation algorithm However one can set the maximum number of iterations with the argument `maxiter` For each iteration time complexity is $O(n_{\text{components}} \times n_{\text{samples}} \times \min(n_{\text{samples}}, n_{\text{features}}))$

$\times \min(n_{\text{samples}}, n_{\text{features}})$

Transform

Here the transform operation returns $n_{\text{components}}$ therefore its time complexity equals $n_{\text{components}}$

$n_{\text{features}} \times n_{\text{sample_test}}$ There is no added space complexity in the operation

References

317 Gaussian Processes

Gaussian Processes GP are a generic supervised learning method designed to solve regression and probabilistic classification problems

The advantages of Gaussian processes are

- The prediction interpolates the observations at least for regular kernels
- The prediction is probabilistic Gaussian so that one can compute empirical confidence intervals and decide based on those if one should refit online fitting adaptive fitting the prediction in some region of interest
- Versatile different kernels can be specified Common kernels are provided but it is also possible to specify custom kernels

¹"Neighbourhood Components Analysis" Advances in Neural Information Processing Systems V ol 17 May 2005 pp 513-520

256 Chapter 3 User Guide

The disadvantages of Gaussian processes include

- They are not sparse ie they use the whole samplesfeatures information to perform the prediction
- They lose efficiency in high dimensional spaces – namely when the number of features exceeds a few dozens

Gaussian Process Regression GPR

TheGaussianProcessRegressor implements Gaussian processes GP for regression purposes For this the

prior of the GP needs to be specified The prior mean is assumed to be constant and zero for normalizeyFalse or the training data’s mean for normalizeyTrue The prior’s covariance is specified by passing a kernel object

The hyperparameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the log

marginallikelihood LML based on the passed optimizer As the LML may have multiple local optima the

optimizer can be started repeatedly by specifying nrestartsoptimizer The first run is always conducted

starting from the initial hyperparameter values of the kernel subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values If the initial hyperparameters should be kept

fixedNone can be passed as optimizer

The noise level in the targets can be specified by passing it via the parameter alpha either globally as a scalar or

per datapoint Note that a moderate noise level can also be helpful for dealing with numeric issues during fitting as

it is effectively implemented as Tikhonov regularization ie by adding it to the diagonal of the kernel matrix An

alternative to specifying the noise level explicitly is to include a WhiteKernel component into the kernel which can

estimate the global noise level from the data see example below

The implementation is based on Algorithm 21 of RW2006 In addition to the API (Application Programming Interface) of standard scikitlearn estimators

GaussianProcessRegressor

- allows prediction without prior fitting based on the GP prior
- provides an additional method sampleyX which evaluates samples drawn from the GPR prior or posterior at given inputs
- exposes a method logmarginallikelihoodtheta which can be used externally for other ways of selecting hyperparameters eg via Markov chain Monte Carlo

GPR examples

GPR with noiselevel estimation

This example illustrates that GPR with a sumkernel including a WhiteKernel can estimate the noise level of data An

illustration of the logmarginallikelihood LML landscape shows that there exist two local maxima of LML

The first corresponds to a model with a high noise level and a large length scale which explains all variations in the data by noise

The second one has a smaller noise level and shorter length scale which explains most of the variation by the noise free functional relationship The second model has a higher likelihood however depending on the initial value for the hyperparameters the gradientbased optimization might also converge to the highnoise solution It is thus important

to repeat the optimization several times for different initializations

Comparison of GPR and Kernel Ridge Regression

Both kernel ridge regression KRR and GPR learn a target function by employing internally the “kernel trick” KRR

learns a linear function in the space induced by the respective kernel which corresponds to a nonlinear function in

the original space The linear function in the kernel space is chosen based on the meansquared error loss with ridge regularization GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses

scikitlearn user guide Release 0213

the observed training data to define a likelihood function Based on Bayes theorem a Gaussian posterior distribution over target functions is defined whose mean is used for prediction

A major difference is that GPR can choose the kernel's hyperparameters based on gradient ascent on the marginal likelihood function while KRR needs to perform a grid search on a crossvalidated loss function meansquared error loss A further difference is that GPR learns a generative probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions

The following figure illustrates both methods on an artificial dataset which consists of a sinusoidal target function and strong noise The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel which is suited for learning periodic functions The kernel's hyperparameters control the smoothness lengthscale and periodicity of the kernel periodicity Moreover the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR

The figure shows that both methods learn reasonable models of the target function GPR correctly identifies the periodicity of the function to be roughly $2\pi \times 628$ while KRR chooses the doubled periodicity 4π Besides that GPR provides reasonable confidence bounds on the prediction which are not available for KRR A major difference between the two methods is the time required for fitting and predicting while fitting KRR is fast in principle the gridsearch for hyperparameter optimization scales exponentially with the number of hyperparameters "curse of dimensionality" The gradientbased optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerable faster on this example with 3dimensional hyperparameter space The time for predicting is similar however generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean

GPR on Mauna Loa CO2 data

This example is based on Section 543 of RW2006 It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the logmarginallikelihood The data consists of the monthly average atmospheric CO2 concentrations in parts per million by volume ppmv collected at the Mauna Loa Observatory in Hawaii between 1958 and 1997 The objective is to model the CO2 concentration as a function of the time t

The kernel is composed of several terms that are responsible for explaining different properties of the signal

scikitlearn user guide Release 0213

- a long term smooth rising trend is to be explained by an RBF (Radial Basis Function) kernel The RBF (Radial Basis Function) kernel with a large lengthscale enforces this component to be smooth it is not enforced that the trend is rising which leaves this choice to the GP The specific lengthscale and the amplitude are free hyperparameters
 - a seasonal component which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year The lengthscale of this periodic component controlling its smoothness is a free parameter In order to allow decaying away from exact periodicity the product with an RBF (Radial Basis Function) kernel is taken The lengthscale of this RBF (Radial Basis Function) component controls the decay time and is a further free parameter
 - smaller medium term irregularities are to be explained by a RationalQuadratic kernel component whose lengthscale and alpha parameter which determines the diffuseness of the lengthscales are to be determined According to RW2006 these irregularities can better be explained by a RationalQuadratic than an RBF (Radial Basis Function) kernel component probably because it can accommodate several lengthscales
 - a “noise” term consisting of an RBF (Radial Basis Function) kernel contribution which shall explain the correlated noise components such as local weather phenomena and a WhiteKernel contribution for the white noise The relative amplitudes and the RBF (Radial Basis Function)’s length scale are further free parameters
- Maximizing the logmarginallikelihood after subtracting the target’s mean yields the following kernel with an LML of 83214

```
3442RBFlengthscale418
 3272RBFlengthscale180 ExpSineSquaredlengthscale144
periodicity1
 04462RationalQuadraticalpha177 lengthscale0957
 01972RBFlengthscale0138 WhiteKernelnoiselevel00336
```

Thus most of the target signal 344ppm is explained by a longterm rising trend lengthscale 418 years The periodic component has an amplitude of 327ppm a decay time of 180 years and a lengthscale of 144 The long decay time indicates that we have a locally very close to periodic seasonal component The correlated noise has an amplitude of 0197ppm with a length scale of 0138 years and a whitenoise contribution of 0197ppm Thus the overall noise level is very small indicating that the data can be very well explained by the model The figure shows also that the model makes very confident predictions until around 2015

Gaussian Process Classification GPC

TheGaussianProcessClassifier implements Gaussian processes GP for classification purposes more specifically for probabilistic classification where test predictions take the form of class probabilities GaussianProcessClassifier places a GP prior on a latent function f which is then squashed through a link function to obtain the probabilistic classification The latent function f is a so called nuisance function whose values are not observed and are not relevant by themselves Its purpose is to allow a convenient formulation of the model and f is removed integrated out during prediction GaussianProcessClassifier implements the logistic link function for which the integral cannot be computed analytically but is easily approximated in the binary case

In contrast to the regression setting the posterior of the latent function f is not Gaussian even for a GP prior since a Gaussian likelihood is inappropriate for discrete class labels Rather a nonGaussian likelihood corresponding to the logistic link function logit is used GaussianProcessClassifier approximates the nonGaussian posterior with a Gaussian based on the Laplace approximation More details can be found in Chapter 3 of RW2006

The GP prior mean is assumed to be zero The prior’s covariance is specified by passing a kernel object The hyperparameters of the kernel are optimized during fitting of GaussianProcessRegressor by maximizing the logmarginal likelihood LML based on the passed optimizer As the LML may have multiple local optima the optimizer can be started repeatedly by specifying nrestartsoptimizer The first run is always conducted starting from the initial hyperparameter values of the kernel subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values If the initial hyperparameters should be kept fixed None can be passed as optimizer

GaussianProcessClassifier supports multiclass classification by performing either oneversusrest or oneversusone based training and prediction In oneversusrest one binary Gaussian process classifier is fitted for each class which is trained to separate this class from the rest In “onevsone” one binary Gaussian process classifier is fitted for each pair of classes which is trained to separate these two classes The predictions of these binary predictors are combined into multiclass predictions See the section on multiclass classification for more details In the case of Gaussian process classification “onevsone” might be computationally cheaper since it has to solve many problems involving only a subset of the whole training set rather than fewer problems on the whole dataset Since Gaussian process classification scales cubically with the size of the dataset this might be considerably faster How ever note that “onevsone” does not support predicting probability estimates but only plain predictions Moreover note thatGaussianProcessClassifier does not yet implement a true multiclass Laplace approximation internally but as discussed above is based on solving several binary classification tasks internally which are combined using oneversusrest or oneversusone

GPC examples

Probabilistic predictions with GPC

This example illustrates the predicted probability of GPC for an RBF (Radial Basis Function) kernel with different choices of the hyperparameters The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum logmarginallikelihood LML

While the hyperparameters chosen by optimizing LML have a considerable larger LML they perform slightly worse according to the logloss on test data The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries which is good but have predicted probabilities close to 05 far away from the class boundaries which is bad This undesirable effect is caused by the Laplace approximation used internally by GPC

The second figure shows the logmarginallikelihood for different choices of the kernel’s hyperparameters highlighting the two choices of the hyperparameters used in the first figure by black dots

Illustration of GPC on the XOR dataset

This example illustrates GPC on XOR data Compared are a stationary isotropic kernel RBF (Radial Basis Function) and a nonstationary kernel DotProduct On this particular dataset the DotProduct kernel obtains considerably better results because the classboundaries are linear and coincide with the coordinate axes In practice however stationary kernels such asRBF often obtain better results

Gaussian process classification GPC on iris dataset

This example illustrates the predicted probability of GPC for an isotropic and anisotropic RBF (Radial Basis Function) kernel on a two dimensional version for the irisdataset This illustrates the applicability of GPC to nonbinary classification The anisotropic RBF (Radial Basis Function) kernel obtains slightly higher logmarginallikelihood by assigning different lengthscales to the two feature dimensions

Kernels for Gaussian Processes

Kernels also called “covariance functions” in the context of GPs are a crucial ingredient of GPs which determine the shape of prior and posterior of the GP They encode the assumptions on the function being learned by defining the “similarity” of two datapoints combined with the assumption that similar datapoints should have similar target values Two categories of kernels can be distinguished stationary kernels depend only on the distance of two datapoints and not on their absolute values $k(x, y) = k(x - y)$ and are thus invariant to translations in the input space

while nonstationary kernels depend also on the specific values of the datapoints Stationary kernels can further be subdivided into isotropic and anisotropic kernels where isotropic kernels are also invariant to rotations in the input space For more details we refer to Chapter 4 of RW2006

Gaussian Process Kernel API (Application Programming Interface)

The main usage of a Kernel is to compute the GP's covariance between datapoints For this the method call of the kernel can be called This method can either be used to compute the "autocovariance" of all pairs of datapoints in a 2d array X or the "crosscovariance" of all combinations of datapoints of a 2d array X with datapoints in a 2d array Y The following identity holds true for all kernels k except for the WhiteKernel $k_X(X, X) = Y_X Y_X$

If only the diagonal of the autocovariance is being used the method diag of a kernel can be called which is more computationally efficient than the equivalent call to call npdiagkX X kdiagX

Kernels are parameterized by a vector θ of hyperparameters These hyperparameters can for instance control length scales or periodicity of a kernel see below All kernels support computing analytic gradients of the kernel's autocovariance with respect to θ via setting evalgradient True in the call method This gradient is used by the Gaussian process both regressor and classifier in computing the gradient of the logmarginallikelihood which in turn is used to determine the value of θ which maximizes the logmarginallikelihood via gradient ascent For each hyperparameter the initial value and the bounds need to be specified when creating an instance of the kernel The current value of θ can be get and set via the property theta of the kernel object Moreover the bounds of the hyperparameters can be accessed by the property bounds of the kernel Note that both properties theta and bounds return logtransformed values of the internally used values since those are typically more amenable to gradientbased optimization The specification of each hyperparameter is stored in the form of an instance of Hyperparameter in the respective kernel Note that a kernel using a hyperparameter with name "x" must have the attributes selfx and selfxbounds

The abstract base class for all kernels is Kernel Kernel implements a similar interface as Estimator providing the methods getparams setparams and clone This allows setting kernel values also via meta estimators such as Pipeline or GridSearch Note that due to the nested structure of kernels by applying kernel operators see below the names of kernel parameters might become relatively complicated In general for a binary kernel operator parameters of the left operand are prefixed with k1 and parameters of the right operand with k2 An additional convenience method is clonewiththetatheta which returns a cloned version of the kernel

All Gaussian process kernels are interoperable with sklearn.metrics.pairwise and vice versa instances of subclasses of Kernel can be passed as metric to pairwise.kernels from sklearn.metrics.pairwise Moreover kernel functions from pairwise can be used as GP kernels by using the wrapper class PairwiseKernel The only caveat is that the gradient of the hyperparameters is not analytic but numeric and all those kernels support only isotropic distances The parameter gamma is considered to be a hyperparameter and may be optimized The other kernel parameters are set directly at initialization and are kept fixed

Basic kernels

The ConstantKernel kernel can be used as part of a Product kernel where it scales the magnitude of the other factor kernel or as part of a Sum kernel where it modifies the mean of the Gaussian process It depends on a parameter γ It is defined as

$$k(x, y) = \gamma \exp(-\gamma \sqrt{\sum_{i=1}^n (x_i - y_i)^2})$$

The main usecase of the WhiteKernel kernel is as part of a sum kernel where it explains the noise component of the signal Tuning its parameter ν corresponds to estimating the noise level It is defined as

$$k(x, y) = \nu \text{ if } x = y \text{ else } 0$$

Kernel operators

Kernel operators take one or two base kernels and combine them into a new kernel The Sum kernel takes two kernels k_1 and k_2 and combines them via $k(x, y) = k_1(x, y) + k_2(x, y)$ The Product kernel takes two kernels k_1

and σ^2 and combines them via $\frac{1}{2\sigma^2} \exp(-\frac{1}{2\sigma^2} \|x - x'\|^2)$. The Exponentiation kernel takes one base kernel and a scalar parameter σ^2 and combines them via $\exp(-\sigma^2 \text{base_kernel}(x, x'))$.

Radialbasis function RBF (Radial Basis Function) kernel

The RBF kernel is a stationary kernel. It is also known as the “squared exponential” kernel. It is parameterized by a lengthscale parameter $\ell > 0$ which can either be a scalar isotropic variant of the kernel or a vector with the same number of dimensions as the inputs x . Anisotropic variant of the kernel. The kernel is given by

$$\frac{1}{(2\pi\ell^2)^{D/2}} \exp\left(-\frac{1}{2\ell^2} \|x - x'\|^2\right)$$

This kernel is infinitely differentiable which implies that GPs with this kernel as covariance function have mean square derivatives of all orders and are thus very smooth. The prior and posterior of a GP resulting from an RBF (Radial Basis Function) kernel are shown in the following figure.

Matérn kernel

The Matérn kernel is a stationary kernel and a generalization of the RBF (Radial Basis Function) kernel. It has an additional parameter ν which controls the smoothness of the resulting function. It is parameterized by a lengthscale parameter $\ell > 0$ which can either be a scalar isotropic variant of the kernel or a vector with the same number of dimensions as the inputs x . Anisotropic variant of the kernel. The kernel is given by

$$\frac{2^{D/2 + \nu} \Gamma(\nu)}{\sqrt{\ell} \Gamma(\nu + 1/2)} \left(\frac{\sqrt{2\nu}}{\ell}\right)^{2\nu} K_{\nu}\left(\frac{\sqrt{2\nu}}{\ell} \|x - x'\|\right)$$

As $\nu \rightarrow \infty$ the Matérn kernel converges to the RBF (Radial Basis Function) kernel. When $\nu = 1/2$ the Matérn kernel becomes identical to the absolute exponential kernel, i.e.

$$\frac{1}{2\ell} \exp\left(-\frac{\|x - x'\|}{\ell}\right)$$

In particular, $\nu = 3/2$

$$\frac{3}{4\ell^2} \exp\left(-\frac{\sqrt{3}}{\ell} \|x - x'\|\right)$$
$$\text{and } \nu = 5/2$$
$$\frac{15}{32\ell^5} \exp\left(-\frac{\sqrt{5}}{\ell} \|x - x'\|\right)$$

are popular choices for learning functions that are not infinitely differentiable as assumed by the RBF (Radial Basis Function) kernel but at least once $\nu = 3/2$ or twice differentiable $\nu = 5/2$.

The flexibility of controlling the smoothness of the learned function via ν allows adapting to the properties of the true underlying functional relation. The prior and posterior of a GP resulting from a Matérn kernel are shown in the following figure.

See RW2006, pp. 84 for further details regarding the different variants of the Matérn kernel.

Rational quadratic kernel

TheRationalQuadratic kernel can be seen as a scale mixture an infinite sum of RBF (Radial Basis Function) kernels with different characteristic lengthscales It is parameterized by a lengthscale parameter ℓ 0and a scale mixture parameter κ 0 Only the isotropic variant where ℓ is a scalar is supported at the moment The kernel is given by

$$k(x, y) = \frac{1}{2\sqrt{\kappa}} \int_0^\infty \exp\left(-\frac{\sqrt{\kappa} \|x - y\|}{2\ell} - \frac{t}{2\kappa}\right) dt$$

The prior and posterior of a GP resulting from a RationalQuadratic kernel are shown in the following figure

ExpSineSquared kernel

TheExpSineSquared kernel allows modeling periodic functions It is parameterized by a lengthscale parameter $\ell > 0$ and a periodicity parameter $p > 0$ Only the isotropic variant where ℓ is a scalar is supported at the moment

The kernel is given by

$$k(x, y) = \exp\left(-2 \sin^2\left(\frac{\pi}{p} \frac{\|x - y\|}{\ell}\right)\right)$$

The prior and posterior of a GP resulting from an ExpSineSquared kernel are shown in the following figure

DotProduct kernel

TheDotProduct kernel is nonstationary and can be obtained from linear regression by putting $\gamma_0=1$ priors on the coefficients of $\gamma_0=1$ and a prior of $\gamma_0=1$

on the bias The DotProduct kernel is invariant to a

rotation of the coordinates about the origin but not translations It is parameterized by a parameter γ_0

For $\gamma_0=1$

0 0

the kernel is called the homogeneous linear kernel otherwise it is inhomogeneous The kernel is given by

$$k(x, y) = \gamma_0 + \gamma_1 x \cdot y$$

TheDotProduct kernel is commonly combined with exponentiation An example with exponent 2 is shown in the following figure

318 Cross decomposition

The cross decomposition module contains two main families of algorithms the partial least squares PLS and the canonical correlation analysis CCA

These families of algorithms are useful to find linear relations between two multivariate datasets the X and Y arguments of the fit method are 2D arrays

Cross decomposition algorithms find the fundamental relations between two matrices X and Y They are latent variable approaches to modeling the covariance structures in these two spaces They will try to find the multidimensional direction in the X space that explains the maximum multidimensional variance direction in the Y space PLS regression is particularly suited when the matrix of predictors has more variables than observations and when there is multicollinearity among X values By contrast standard regression will fail in these cases

Classes included in this module are PLSRegression PLSCanonical CCA and PLSSVD

Examples

31 Supervised learning 275

Naive Bayes methods are a set of supervised learning algorithms based on applying Bayes’ theorem with the “naive” assumption of conditional independence between every pair of features given the value of the class variable Bayes’ theorem states the following relationship given class variable c and dependent feature vector x_1 through x_n

$$P(c) \prod_{i=1}^n P(x_i | c)$$

Using the naive conditional independence assumption that

$$P(x_1, \dots, x_n | c) = \prod_{i=1}^n P(x_i | c)$$

for all c this relationship is simplified to

$$P(c) \prod_{i=1}^n P(x_i | c)$$

Since $P(c)$ is constant given the input we can use the following classification rule

$$P(c) \propto \prod_{i=1}^n P(x_i | c)$$

$$\downarrow$$
$$\arg \max_c \prod_{i=1}^n P(x_i | c)$$

and we can use Maximum A Posteriori MAP estimation to estimate $P(c)$ and $P(x_i | c)$ the former is then the relative frequency of class c in the training set

The different naive Bayes classifiers differ mainly by the assumptions they make regarding the distribution of x_i

In spite of their apparently oversimplified assumptions naive Bayes classifiers have worked quite well in many real world situations famously document classification and spam filtering They require a small amount of training data to estimate the necessary parameters For theoretical reasons why naive Bayes works well and on which types of data it does see the references below

Naive Bayes learners and classifiers can be extremely fast compared to more sophisticated methods The decoupling of the class conditional feature distributions means that each distribution can be independently estimated as a one dimensional distribution This in turn helps to alleviate problems stemming from the curse of dimensionality On the flip side although naive Bayes is known as a decent classifier it is known to be a bad estimator so the probability outputs from predict_proba are not to be taken too seriously

276 Chapter 3 User Guide

Gaussian Naive Bayes

GaussianNB implements the Gaussian Naive Bayes algorithm for classification The likelihood of the features is assumed to be Gaussian

$$\frac{1}{\sqrt{2\pi\sigma^2}} \exp\left(-\frac{x^2}{2\sigma^2}\right)$$

The parameters μ and σ are estimated using maximum likelihood

```
from sklearn import datasets
iris = datasets.load_iris()
from sklearn.naive_bayes import GaussianNB
gnb = GaussianNB()
ypred = gnb.fit(iris.data, iris.target).predict(iris.data)
print("Number of mislabeled points out of a total %d points: %d" %
      (iris.data.shape[0], iris.target != ypred).sum())
# Number of mislabeled points out of a total 150 points: 6
```

Multinomial Naive Bayes

MultinomialNB implements the naive Bayes algorithm for multinomially distributed data and is one of the two classic naive Bayes variants used in text classification where the data are typically represented as word vector counts although tfidf vectors are also known to work well in practice The distribution is parametrized by vectors θ and ϕ for each class c where ϕ is the number of features in text classification the size of the vocabulary and θ_c is the probability of feature i appearing in a sample belonging to class c

The parameters θ is estimated by a smoothed version of maximum likelihood ie relative frequency counting

$$\theta_{ci} = \frac{x_{ci} + 1}{\sum_j x_{cj} + V}$$

where x_{ci} is the number of times feature i appears in a sample of class c in the training set V and $V = \sum_i x_{ci}$ is the total count of all features for class c

The smoothing priors $\theta_{ci} \geq 0$ accounts for features not present in the learning samples and prevents zero probabilities in further computations Setting $\alpha = 1$ is called Laplace smoothing while $\alpha = 1/V$ is called Lidstone smoothing

Complement Naive Bayes

ComplementNB implements the complement naive Bayes CNB algorithm CNB is an adaptation of the standard multinomial naive Bayes MNB algorithm that is particularly suited for imbalanced data sets Specifically CNB uses statistics from the complement of each class to compute the model's weights The inventors of CNB show empirically that the parameter estimates for CNB are more stable than those for MNB Further CNB regularly outperforms MNB often by a considerable margin on text classification tasks The procedure for calculating the weights is as follows

$$w_c = \frac{\sum_{i \notin c} x_{ci}}{\sum_{i \notin c} x_{ci} + \alpha}$$
$$w_c = \log \frac{\sum_{i \notin c} x_{ci}}{\sum_{i \notin c} x_{ci} + \alpha}$$

where the summations are over all documents i not in class c α is either the count or tfidf value of term i in document c α is a smoothing hyperparameter like that found in MNB and $V = \sum_i x_{ci}$

The second normalization

scikitlearn user guide Release 0213

addresses the tendency for longer documents to dominate parameter estimates in MNB The classification rule is

$$\hat{c} = \arg \min_c \sum_{i=1}^n \mathbb{I}(y_i \neq c)$$

ie a document is assigned to the class that is the poorest complement match

References

- Rennie J D Shih L Teevan J Karger D R 2003 Tackling the poor assumptions of naive bayes text classifiers In ICML V ol 3 pp 616623

Bernoulli Naive Bayes

BernoulliNB implements the naive Bayes training and classification algorithms for data that is distributed according to multivariate Bernoulli distributions ie there may be multiple features but each one is assumed to be a binaryvalued Bernoulli boolean variable Therefore this class requires samples to be represented as binaryvalued feature vectors if handed any other kind of data a BernoulliNB instance may binarize its input depending on the binarize parameter

The decision rule for Bernoulli naive Bayes is based on

$$\hat{c} = \arg \min_c \sum_{i=1}^n \mathbb{I}(y_i \neq c)$$

which differs from multinomial NB’s rule in that it explicitly penalizes the nonoccurrence of a feature x_{ij} that is an indicator for class c where the multinomial variant would simply ignore a nonoccurring feature

In the case of text classification word occurrence vectors rather than word count vectors may be used to train and use this classifier BernoulliNB might perform better on some datasets especially those with shorter documents

It is advisable to evaluate both models if time permits

Outofcore naive Bayes model fitting

Naive Bayes models can be used to tackle large scale classification problems for which the full training set might not fit in memory To handle this case MultinomialNB BernoulliNB andGaussianNB expose apartialfit method that can be used incrementally as done with other classifiers as demonstrated in Outofcore classification of text documents All naive Bayes classifiers support sample weighting

Contrary to the fit method the first call to partialfit needs to be passed the list of all the expected class labels

For an overview of available strategies in scikitlearn see also the outofcore learning documentation

scikitlearn user guide Release 0213

Note Thepartialfit method call of naive Bayes models introduces some computational overhead It is recommended to use data chunk sizes that are as large as possible that is as the available RAM allows

3110 Decision Trees

Decision Trees DTs are a nonparametric supervised learning method used for classification andregression The goal is to create a model that predicts the value of a target variable by learning simple decision rules inferred from the data features

For instance in the example below decision trees learn from data to approximate a sine curve with a set of ifthenelse decision rules The deeper the tree the more complex the decision rules and the fitter the model

Some advantages of decision trees are

- Simple to understand and to interpret Trees can be visualised
- Requires little data preparation Other techniques often require data normalisation dummy variables need to be created and blank values to be removed Note however that this module does not support missing values
- The cost of using the tree ie predicting data is logarithmic in the number of data points used to train the tree
- Able to handle both numerical and categorical data Other techniques are usually specialised in analysing datasets that have only one type of variable See algorithms for more information
- Able to handle multioutput problems
- Uses a white box model If a given situation is observable in a model the explanation for the condition is easily explained by boolean logic By contrast in a black box model eg in an artificial neural network results may be more difficult to interpret
- Possible to validate a model using statistical tests That makes it possible to account for the reliability of the model

31 Supervised learning 279

scikitlearn user guide Release 0213

- Performs well even if its assumptions are somewhat violated by the true model from which the data were generated

The disadvantages of decision trees include

- Decisiontree learners can create overcomplex trees that do not generalise the data well This is called overfitting Mechanisms such as pruning not currently supported setting the minimum number of samples required at a leaf node or setting the maximum depth of the tree are necessary to avoid this problem
- Decision trees can be unstable because small variations in the data might result in a completely different tree being generated This problem is mitigated by using decision trees within an ensemble
- The problem of learning an optimal decision tree is known to be NPcomplete under several aspects of optimality and even for simple concepts Consequently practical decisiontree learning algorithms are based on heuristic algorithms such as the greedy algorithm where locally optimal decisions are made at each node Such algorithms cannot guarantee to return the globally optimal decision tree This can be mitigated by training multiple trees in an ensemble learner where the features and samples are randomly sampled with replacement
- There are concepts that are hard to learn because decision trees do not express them easily such as XOR parity or multiplexer problems
- Decision tree learners create biased trees if some classes dominate It is therefore recommended to balance the dataset prior to fitting with the decision tree

Classification

DecisionTreeClassifier is a class capable of performing multiclass classification on a dataset As with other classifiers DecisionTreeClassifier takes as input two arrays an array X sparse or dense of sizensamples nfeatures holding the training samples and an array Y of integer values size nsamples holding the class labels for the training samples

```
from sklearn import tree
X = [[0, 0, 1, 1],
     [0, 1, 0, 1]]
Y = [0, 1]
clf = tree.DecisionTreeClassifier()
clf = clf.fit(X, Y)
```

After being fitted the model can then be used to predict the class of samples

```
clf.predict([2, 2])
array([1])
Alternatively the probability of each class can be predicted which is the fraction of training samples of the same class in a leaf
clf.predict_proba([2, 2])
array([[0, 1]])
```

DecisionTreeClassifier is capable of both binary where the labels are 1 1 classification and multiclass where the labels are 0 K1 classification

Using the Iris dataset we can construct a tree as follows

```
from sklearn.datasets import load_iris
from sklearn import tree
iris = load_iris()
clf = tree.DecisionTreeClassifier()
clf = clf.fit(iris.data, iris.target)
```

scikitlearn user guide Release 0213

Once trained you can plot the tree with the `plottree` function

`treeplottree(clf.fit(iris.data, iris.target))`

We can also export the tree in Graphviz format using the `exportgraphviz` exporter. If you use the conda package manager, the graphviz binaries

and the python package can be installed with

`conda install python-graphviz`

Alternatively, binaries for graphviz can be downloaded from the graphviz project homepage and the Python wrapper

installed from pypi with `pip install graphviz`

Below is an example graphviz export of the above tree trained on the entire iris dataset; the results are saved in an output file `iris.pdf`:

```
import graphviz
dotdata = tree.export_graphviz(clf, out_file=None)
graph = graphviz.Source(dotdata)
graph.render('iris')
```

The `export_graphviz` exporter also supports a variety of aesthetic options including coloring nodes by their class or value for regression and using explicit variable and class names if desired. Jupyter notebooks also render these plots inline automatically.

```
dotdata = tree.export_graphviz(clf, out_file=None,
                              feature_names=iris.feature_names,
                              class_names=iris.target_names,
                              filled=True, rounded=True,
                              special_characters=True)
graph = graphviz.Source(dotdata)
graph
```

31 Supervised learning 281

scikitlearn user guide Release 0213

Alternatively the tree can also be exported in textual format with the function `exporttext`. This method doesn't require the installation of external libraries and is more compact.

```
from sklearn.datasets import load_iris
from sklearn.tree import DecisionTreeClassifier
from sklearn.tree.export import export_text

iris = load_iris()
X = iris.data
y = iris.target

decisiontree = DecisionTreeClassifier(random_state=0, max_depth=2)
decisiontree.fit(X, y)

r = export_text(decisiontree, feature_names=iris.feature_names)
print(r)

petal width cm 0.80
class 0
petal width cm 0.80
petal width cm 1.75
class 1
petal width cm 1.75
class 2
```

Examples

- Plot the decision surface of a decision tree on the iris dataset
- Understanding the decision tree structure

Regression

Decision trees can also be applied to regression problems using the `DecisionTreeRegressor` class.

scikitlearn user guide Release 0213

As in the classification setting the fit method will take as argument arrays X and y only that in this case y is expected to have floating point values instead of integer values

```
from sklearn import tree
X = [[0, 0, 2, 2],
     [0.5, 2.5]]
clf = tree.DecisionTreeRegressor()
clf.fit(X, y)
clf.predict([[1, 1]])
array([0.5])
```

Examples

•Decision Tree Regression

Multioutput problems

A multioutput problem is a supervised learning problem with several outputs to predict that is when Y is a 2d array of size n_samples x n_outputs

When there is no correlation between the outputs a very simple way to solve this kind of problem is to build n independent models ie one for each output and then to use those models to independently predict each one of the n outputs However because it is likely that the output values related to the same input are themselves correlated an often better way is to build a single model capable of predicting simultaneously all n outputs First it requires lower training time since only a single estimator is built Second the generalization accuracy of the resulting estimator may often be increased

With regard to decision trees this strategy can readily be used to support multioutput problems This requires the following changes

- Store n output values in leaves instead of 1
- Use splitting criteria that compute the average reduction across all n outputs

This module offers support for multioutput problems by implementing this strategy in both

DecisionTreeClassifier and DecisionTreeRegressor If a decision tree is fit on an output array Y of size n_samples x n_outputs then the resulting estimator will

- Output n_output values upon predict
- Output a list of n_output arrays of class probabilities upon predict_proba

The use of multioutput trees for regression is demonstrated in Multioutput Decision Tree Regression In this example the input X is a single real value and the outputs Y are the sine and cosine of X

The use of multioutput trees for classification is demonstrated in Face completion with a multioutput estimators In this example the inputs X are the pixels of the upper half of faces and the outputs Y are the pixels of the lower half of those faces

Examples

•Multioutput Decision Tree Regression

•Face completion with a multioutput estimators

Complexity

In general the run time cost to construct a balanced binary tree is $O(n \log n)$ and query time $O(\log n)$. Although the tree construction algorithm attempts to generate balanced trees they will not always be balanced. Assuming that the subtrees remain approximately balanced the cost at each node consists of searching through n to find the feature that offers the largest reduction in entropy. This has a cost of $O(n \log n)$ at each node leading to a total cost over the entire trees by summing the cost at each node of $O(n^2 \log n)$.

Scikitlearn offers a more efficient implementation for the construction of decision trees. A naive implementation as above would recompute the class label histograms for classification or the means for regression at for each new split point along a given feature. Presorting the feature over all relevant samples and retaining a running label count will reduce the complexity at each node to $O(n \log n)$ which results in a total cost of $O(n^2 \log n)$. This is an option for all tree based algorithms. By default it is turned on for gradient boosting where in general it makes training faster but turned off for all other algorithms as it tends to slow down training when training deep trees.

Tips on practical use

- Decision trees tend to overfit on data with a large number of features. Getting the right ratio of samples to number of features is important since a tree with few samples in high dimensional space is very likely to overfit.

scikitlearn user guide Release 0213

- Consider performing dimensionality reduction PCA (Principal Component Analysis) ICA or Feature selection beforehand to give your tree a better chance of finding features that are discriminative
- Understanding the decision tree structure will help in gaining more insights about how the decision tree makes predictions which is important for understanding the important features in the data
- Visualise your tree as you are training by using the export function Use maxdepth3 as an initial tree depth to get a feel for how the tree is fitting to your data and then increase the depth
- Remember that the number of samples required to populate the tree doubles for each additional level the tree grows to Use maxdepth to control the size of the tree to prevent overfitting
- Use minsamplessplit or minsamplesleaf to ensure that multiple samples inform every decision in the tree by controlling which splits will be considered A very small number will usually mean the tree will overfit whereas a large number will prevent the tree from learning the data Try minsamplesleaf5 as an initial value If the sample size varies greatly a float number can be used as percentage in these two parameters While minsamplessplit can create arbitrarily small leaves minsamplesleaf guarantees that each leaf has a minimum size avoiding low variance overfit leaf nodes in regression problems For classification with few classes minsamplesleaf1 is often the best choice
- Balance your dataset before training to prevent the tree from being biased toward the classes that are dominant Class balancing can be done by sampling an equal number of samples from each class or preferably by normalizing the sum of the sample weights sampleweight for each class to the same value Also note that weightbased prepruning criteria such as minweightfractionleaf will then be less biased toward dominant classes than criteria that are not aware of the sample weights like minsamplesleaf
- If the samples are weighted it will be easier to optimize the tree structure using weightbased prepruning criterion such as minweightfractionleaf which ensure that leaf nodes contain at least a fraction of the overall sum of the sample weights
- All decision trees use npfloat32 arrays internally If training data is not in this format a copy of the dataset will be made
- If the input matrix X is very sparse it is recommended to convert to sparse cscmatrix before calling fit and sparsecsrmatrix before calling predict Training time can be orders of magnitude faster for a sparse matrix input compared to a dense matrix when features have zero values in most of the samples

Tree algorithms ID3 C45 C50 and CART

What are all the various decision tree algorithms and how do they differ from each other Which one is implemented in scikitlearn

ID3 Iterative Dichotomiser 3 was developed in 1986 by Ross Quinlan The algorithm creates a multiway tree finding for each node ie in a greedy manner the categorical feature that will yield the largest information gain for categorical targets Trees are grown to their maximum size and then a pruning step is usually applied to improve the ability of the tree to generalise to unseen data

C45 is the successor to ID3 and removed the restriction that features must be categorical by dynamically defining a discrete attribute based on numerical variables that partitions the continuous attribute value into a discrete set of intervals C45 converts the trained trees ie the output of the ID3 algorithm into sets of ifthen rules These accuracy of each rule is then evaluated to determine the order in which they should be applied Pruning is done by removing a rule's precondition if the accuracy of the rule improves without it

C50 is Quinlan's latest version release under a proprietary license It uses less memory and builds smaller rulesets than C45 while being more accurate

CART Classification and Regression Trees is very similar to C45 but it differs in that it supports numerical target variables regression and does not compute rule sets CART constructs binary trees using the feature and threshold that yield the largest information gain at each node

31 Supervised learning 287

scikitlearn uses an optimised version of the CART algorithm however scikitlearn implementation does not support categorical variables for now

Mathematical formulation

Given training vectors $x_i \in \mathbb{R}^d$ $i=1 \dots n$ and a label vector $y \in \mathbb{R}$ a decision tree recursively partitions the space such that the samples with the same labels are grouped together

Let the data at node j be represented by D_j For each candidate split $s = (f, \tau)$ consisting of a feature f and threshold τ partition the data into D_{jL} and D_{jR} subsets

$$D_{jL} = \{x_i \in D_j \mid f(x_i) \leq \tau\}$$
$$D_{jR} = \{x_i \in D_j \mid f(x_i) > \tau\}$$

The impurity at j is computed using an impurity function i the choice of which depends on the task being solved classification or regression

$$i(D_j) = i(D_{jL}, D_{jR})$$
$$i(D_j) = i(D_{jL}) + i(D_{jR})$$

Select the parameters that minimises the impurity

$s = \arg\min_{s \in S} i(D_j, s)$
Recurse for subsets D_{jL} and D_{jR} until the maximum allowable depth is reached \max_depth or $n \leq 1$

Classification criteria

If a target is a classification outcome taking on values $0, 1, \dots, K-1$ for node j representing a region R_j with n_j observations let

$$p_{jk} = \frac{1}{n_j} \sum_{i \in R_j} \mathbb{1}_{y_i = k}$$

be the proportion of class k observations in node j

Common measures of impurity are Gini

$$Gini(D_j) = \sum_{k=0}^{K-1} p_{jk}(1 - p_{jk})$$

Entropy

$$Entropy(D_j) = -\sum_{k=0}^{K-1} p_{jk} \log(p_{jk})$$

and Misclassification

$$Misclassification(D_j) = 1 - \max_k p_{jk}$$

where p_{jk} is the training data in node j

Regression criteria

If the target is a continuous value then for node n representing a region R_n with N_n observations common criteria to minimise as for determining locations for future splits are Mean Squared Error which minimizes the L2 error using mean values at terminal nodes and Mean Absolute Error which minimizes the L1 error using median values at terminal nodes

Mean Squared Error

$$\frac{1}{N_n} \sum_{i \in R_n} (y_i - \hat{y}_n)^2$$

Mean Absolute Error

$$\frac{1}{N_n} \sum_{i \in R_n} |y_i - \hat{y}_n|$$

where R_n is the training data in node n

3111 Ensemble methods

The goal of ensemble methods is to combine the predictions of several base estimators built with a given learning algorithm in order to improve generalizability robustness over a single estimator

Two families of ensemble methods are usually distinguished

- In averaging methods the driving principle is to build several estimators independently and then to average their predictions On average the combined estimator is usually better than any of the single base estimator because its variance is reduced

Examples Bagging methods Forests of randomized trees

- By contrast in boosting methods base estimators are built sequentially and one tries to reduce the bias of the combined estimator The motivation is to combine several weak models to produce a powerful ensemble

Examples AdaBoost Gradient Tree Boosting

Bagging metaestimator

In ensemble algorithms bagging methods form a class of algorithms which build several instances of a blackbox estimator on random subsets of the original training set and then aggregate their individual predictions to form a final prediction These methods are used as a way to reduce the variance of a base estimator eg a decision tree by introducing randomization into its construction procedure and then making an ensemble out of it In many cases bagging methods constitute a very simple way to improve with respect to a single model without making it necessary to adapt the underlying base algorithm As they provide a way to reduce overfitting bagging methods work best with strong and complex models eg fully developed decision trees in contrast with boosting methods which usually work best with weak models eg shallow decision trees

Bagging methods come in many flavours but mostly differ from each other by the way they draw random subsets of the training set

- When random subsets of the dataset are drawn as random subsets of the samples then this algorithm is known as Pasting B1999
- When samples are drawn with replacement then the method is known as Bagging B1996
- When random subsets of the dataset are drawn as random subsets of the features then the method is known as Random Subspaces H1998
- Finally when base estimators are built on subsets of both samples and features then the method is known as Random Patches LG2012

In scikitlearn bagging methods are offered as a unified BaggingClassifier metaestimator resp BaggingRegressor taking as input a userspecified base estimator along with parameters specifying the strategy to draw random subsets In particular maxsamples andmaxfeatures control the size of the subsets in terms of samples and features while bootstrap andbootstrapfeatures control whether samples and features are drawn with or without replacement When using a subset of the available samples the generalization accuracy can be estimated with the outofbag samples by setting oobscoreTrue As an example the snippet below illustrates how to instantiate a bagging ensemble of KNeighborsClassifier base estimators each built on random subsets of 50 of the samples and 50 of the features

```
from sklearnensemble import BaggingClassifier
from sklearnneighbors import KNeighborsClassifier
bagging = BaggingClassifier(KNeighborsClassifier
    maxsamples05 maxfeatures05
```

Examples

- Single estimator versus bagging biasvariance decomposition

References

Forests of randomized trees

The sklearnensemble module includes two averaging algorithms based on randomized decision trees the RandomForest algorithm and the ExtraTrees method Both algorithms are perturbandcombine techniques B1998 specifically designed for trees This means a diverse set of classifiers is created by introducing randomness in the classifier construction The prediction of the ensemble is given as the averaged prediction of the individual classifiers

290 Chapter 3 User Guide

scikitlearn user guide Release 0213

As other classifiers forest classifiers have to be fitted with two arrays a sparse or dense array X of size nsamples nfeatures holding the training samples and an array Y of size nsamples holding the target values class labels for the training samples

```
from sklearnensemble import RandomForestClassifier
X 0 0 1 1
Y 0 1
clf RandomForestClassifiernestimators10
clf clffitX Y
```

Like decision trees forests of trees also extend to multioutput problems if Y is an array of size nsamples noutputs

Random Forests

In random forests see RandomForestClassifier andRandomForestRegressor classes each tree in the ensemble is built from a sample drawn with replacement ie a bootstrap sample from the training set Furthermore when splitting each node during the construction of a tree the best split is found either from all input features or a random subset of size maxfeatures See the parameter tuning guidelines for more details The purpose of these two sources of randomness is to decrease the variance of the forest estimator Indeed individual decision trees typically exhibit high variance and tend to overfit The injected randomness in forests yield decision trees with somewhat decoupled prediction errors By taking an average of those predictions some errors can cancel out Random forests achieve a reduced variance by combining diverse trees sometimes at the cost of a slight increase in bias In practice the variance reduction is often significant hence yielding an overall better model In contrast to the original publication B2001 the scikitlearn implementation combines classifiers by averaging their probabilistic prediction instead of letting each classifier vote for a single class

Extremely Randomized Trees

In extremely randomized trees see ExtraTreesClassifier andExtraTreesRegressor classes randomness goes one step further in the way splits are computed As in random forests a random subset of candidate features is used but instead of looking for the most discriminative thresholds thresholds are drawn at random for each candidate feature and the best of these randomlygenerated thresholds is picked as the splitting rule This usually allows to reduce the variance of the model a bit more at the expense of a slightly greater increase in bias

```
from sklearnmodelselection import crossvalscore

Parameters

The main parameters to adjust when using these methods is nestimators andmaxfeatures. The former is the number of trees in the forest. The larger the better but also the longer it will take to compute. In addition note that results will stop getting significantly better beyond a critical number of trees. The latter is the size of the random subsets of features to consider when splitting a node. The lower the greater the reduction of variance but also the greater the increase in bias. Empirical good default values are maxfeaturesNone always considering all features instead of a random subset for regression problems and maxfeaturesqrt using a random subset of sizesqrtnfeatures for classification tasks where nfeatures is the number of features in the data. Good results are often achieved when setting maxdepthNone in combination with minsamplesplit2 ie when fully developing the trees. Bear in mind though that these values are usually not optimal and might result in models that consume a lot of RAM. The best parameter values should always be crossvalidated. In addition note that in random forests bootstrap samples are used by default bootstrapTrue while the default strategy for extratrees is to use the whole dataset bootstrapFalse. When using bootstrap sampling the generalization accuracy can be estimated on the left out or outofbag samples. This can be enabled by setting oobscoreTrue. Note The size of the model with the default parameters is $O(n \log n)$ where n is the number of trees and m is the number of samples. In order to reduce the size of the model you can change these parameters minsamplesplit maxleafnodes maxdepth andminsamplesleaf.

292 Chapter 3 User Guide

Parallelization

Finally this module also features the parallel construction of the trees and the parallel computation of the predictions through the `njobs` parameter. If `njobs=k` then computations are partitioned into `k` jobs and run on `k` cores of the machine. If `njobs=1` then all cores available on the machine are used. Note that because of interprocess communication overhead the speedup might not be linear, ie using `k` jobs will unfortunately not be `k` times as fast. Significant speedup can still be achieved though when building a large number of trees or when building a single tree requires a fair amount of time eg on large datasets.

Examples

- Plot the decision surfaces of ensembles of trees on the iris dataset
- Pixel importances with a parallel forest of trees
- Face completion with a multioutput estimators

Feature importance evaluation

The relative rank ie depth of a feature used as a decision node in a tree can be used to assess the relative importance of that feature with respect to the predictability of the target variable. Features used at the top of the tree contribute to the final prediction decision of a larger fraction of the input samples. The expected fraction of the samples they contribute to can thus be used as an estimate of the relative importance of the features. In scikitlearn the fraction of samples a feature contributes to is combined with the decrease in impurity from splitting them to create a normalized estimate of the predictive power of that feature.

By averaging the estimates of predictive ability over several randomized trees one can reduce the variance of such an estimate and use it for feature selection. This is known as the mean decrease in impurity or MDI. Refer to L2014 for more information on MDI and feature importance evaluation with Random Forests.

The following example shows a color-coded representation of the relative importances of each individual pixel for a face recognition task using an `ExtraTreesClassifier` model.

In practice those estimates are stored as an attribute named `feature_importances_` on the fitted model. This is an array with shape `n_features` whose values are positive and sum to 1.0. The higher the value the more important is the contribution of the matching feature to the prediction function.

Examples

- Pixel importances with a parallel forest of trees
- Feature importances with forests of trees

scikitlearn user guide Release 0213

Totally Random Trees Embedding

RandomTreesEmbedding implements an unsupervised transformation of the data Using a forest of completely random trees RandomTreesEmbedding encodes the data by the indices of the leaves a data point ends up in This index is then encoded in a oneofK manner leading to a high dimensional sparse binary coding This coding can be computed very efficiently and can then be used as a basis for other learning tasks The size and sparsity of the code can be influenced by choosing the number of trees and the maximum depth per tree For each tree in the ensemble the coding contains one entry of one The size of the coding is at most nestimators 2maxdepth the maximum number of leaves in the forest

As neighboring data points are more likely to lie within the same leaf of a tree the transformation performs an implicit nonparametric density estimation

Examples

- Hashing feature transformation using Totally Random Trees
- Manifold learning on handwritten digits Locally Linear Embedding Isomap compares nonlinear dimensionality reduction techniques on handwritten digits
- Feature transformations with ensembles of trees compares supervised and unsupervised tree based feature transformations

See also

Manifold learning techniques can also be useful to derive nonlinear representations of feature space also these approaches focus also on dimensionality reduction

AdaBoost

The module sklearnensemble includes the popular boosting algorithm AdaBoost introduced in 1995 by Freund and Schapire FS1995

The core principle of AdaBoost is to fit a sequence of weak learners ie models that are only slightly better than random guessing such as small decision trees on repeatedly modified versions of the data The predictions from all of them are then combined through a weighted majority vote or sum to produce the final prediction The data modifications at each socalled boosting iteration consist of applying weights w_t to each of the training samples Initially those weights are all set to $w_1 = 1$ so that the first step simply trains a weak learner on the original data For each successive iteration the sample weights are individually modified and the learning algorithm is reapplied to the reweighted data At a given step those training examples that were incorrectly predicted by the boosted model induced at the previous step have their weights increased whereas the weights are decreased for those that were predicted correctly As iterations proceed examples that are difficult to predict receive everincreasing influence Each subsequent weak learner is thereby forced to concentrate on the examples that are missed by the previous ones in the sequence HTF

AdaBoost can be used both for classification and regression problems

- For multiclass classification AdaBoostClassifier implements AdaBoostSAMME and AdaBoostSAMMER ZZRH2009

- For regression AdaBoostRegressor implements AdaBoostR2 D1997

Usage

The following example shows how to fit an AdaBoost classifier with 100 weak learners

```
from sklearnmodelselection import crossvalscore
from sklearndatasets import loadiris
from sklearnensemble import AdaBoostClassifier
```

scikitlearn user guide Release 0213

```
iris loadiris
clf AdaBoostClassifiernestimators100
scores crossvalscoreclf irisdata iristarget cv5
scoresmean
09
```

The number of weak learners is controlled by the parameter nestimators Thelearningrate parameter controls the contribution of the weak learners in the final combination By default weak learners are decision stumps Different weak learners can be specified through the baseestimator parameter The main parameters to tune to obtain good results are nestimators and the complexity of the base estimators eg its depth maxdepth or minimum required number of samples to consider a split minsamplesplit

Examples

- Discrete versus Real AdaBoost compares the classification error of a decision stump decision tree and a boosted decision stump using AdaBoostSAMME and AdaBoostSAMMER
- Multiclass AdaBoosted Decision Trees shows the performance of AdaBoostSAMME and AdaBoost SAMMER on a multiclass problem
- Twoclass AdaBoost shows the decision boundary and decision function values for a nonlinearly separable twoclass problem using AdaBoostSAMME
- Decision Tree Regression with AdaBoost demonstrates regression with the AdaBoostR2 algorithm

Gradient Tree Boosting

Gradient Tree Boosting or Gradient Boosted Regression Trees GBRT is a generalization of boosting to arbitrary differentiable loss functions GBRT is an accurate and effective offtheshelf procedure that can be used for both regression and classification problems Gradient Tree Boosting models are used in a variety of areas including Web search ranking and ecology

The advantages of GBRT are

- Natural handling of data of mixed type heterogeneous features
- Predictive power
- Robustness to outliers in output space via robust loss functions

The disadvantages of GBRT are

- Scalability due to the sequential nature of boosting it can hardly be parallelized

The module sklearnensemble provides methods for both classification and regression via gradient boosted regression trees

Note Scikitlearn 021 introduces two new experimental implementation of gradient boosting trees namely HistGradientBoostingClassifier andHistGradientBoostingRegressor inspired by Light

GBM These fast estimators first bin the input samples Xinto integervalue bins typically 256 bins which tremen dously reduces the number of splitting points to consider and allow the algorithm to leverage integerbased data structures histograms instead of relying on sorted continuous values

scikitlearn user guide Release 0213

The new histogrambased estimators can be orders of magnitude faster than their continuous counterparts when the number of samples is larger than tens of thousands of samples The API (Application Programming Interface) of these new estimators is slightly different and some of the features from GradientBoostingClassifier and GradientBoostingRegressor are not yet supported

These new estimators are still experimental for now their predictions and their API (Application Programming Interface) might change without any deprecation cycle To use them you need to explicitly import enablehistgradientboosting

```
explicitly require this experimental feature
from sklearn.experimental import enablehistgradientboosting
now you can import normally from ensemble
from sklearn.ensemble import HistGradientBoostingClassifier
```

The following guide focuses on GradientBoostingClassifier and GradientBoostingRegressor only which might be preferred for small sample sizes since binning may lead to split points that are too approximate in this setting

Classification

GradientBoostingClassifier supports both binary and multiclass classification The following example shows how to fit a gradient boosting classifier with 100 decision stumps as weak learners

```
from sklearn.datasets import make_hastie102
from sklearn.ensemble import GradientBoostingClassifier
X, y = make_hastie102(random_state=0)
X_train, X_test, y_train, y_test = train_test_split(X, y,
                                                    test_size=0.33,
                                                    random_state=0)
clf = GradientBoostingClassifier(n_estimators=100, learning_rate=10,
                                max_depth=1, random_state=0)
clf.fit(X_train, y_train)
clf.score(X_test, y_test)
```

The number of weak learners ie regression trees is controlled by the parameter n_estimators The size of each tree can be controlled either by setting the tree depth via max_depth or by setting the number of leaf nodes via max_leaf_nodes The learning_rate is a hyperparameter in the range [0, 1] that controls overfitting via shrinkage

Note Classification with more than 2 classes requires the induction of n_classes regression trees at each iteration thus the total number of induced trees equals n_classes * n_estimators For datasets with a large number of classes we strongly recommend to use RandomForestClassifier as an alternative to GradientBoostingClassifier

Regression

GradientBoostingRegressor supports a number of different loss functions for regression which can be specified via the argument loss the default loss function for regression is least squares

```
import numpy as np
from sklearn.metrics import mean_squared_error
from sklearn.datasets import make_friedman1
```

scikitlearn user guide Release 0213

```
from sklearnensemble import GradientBoostingRegressor
X, y = makefriedman1(nsamples=1200, randomstate=0, noise=10)
Xtrain, Xtest, ytrain, ytest = X[0:1000], X[1000:1200], y[0:1000], y[1000:1200]
est = GradientBoostingRegressor(n_estimators=100, learning_rate=0.1,
                                max_depth=1, random_state=0, loss='ls', fit_params={'Xtrain': Xtrain, 'ytrain': ytrain})
est.fit(Xtrain, ytrain)
ytest_pred = est.predict(Xtest)
500
```

The figure below shows the results of applying GradientBoostingRegressor with least squares loss and 500 base learners to the Boston house price dataset. `sklearn.datasets.load_boston`. The plot on the left shows the train and test error at each iteration. The train error at each iteration is stored in the `train_score` attribute of the gradient boosting model. The test error at each iteration can be obtained via the `staged_predict` method which returns a generator that yields the predictions at each stage. Plots like these can be used to determine the optimal number of trees (i.e. `n_estimators`) by early stopping. The plot on the right shows the feature importances which can be obtained via the `feature_importances_` property.

Examples

- Gradient Boosting regression
- Gradient Boosting Out-of-Bag estimates

Fitting additional weak learners

Both `GradientBoostingRegressor` and `GradientBoostingClassifier` support

`warm_start=True` which allows you to add more estimators to an already fitted model.

Controlling the tree size

The size of the regression tree base learners defines the level of variable interactions that can be captured by the gradient boosting model In general a tree of depth h can capture interactions of order h There are two ways in which the size of the individual regression trees can be controlled

If you specify maxdepthh then complete binary trees of depth h will be grown Such trees will have at most 2h leaf nodes and 2h - 1 split nodes

Alternatively you can control the tree size by specifying the number of leaf nodes via the parameter maxleafnodes In this case trees will be grown using bestfirst search where nodes with the highest improve ment in impurity will be expanded first A tree with maxleafnodes k has k - 1 split nodes and thus can model interactions of up to order maxleafnodes - 1

We found that maxleafnodesk gives comparable results to maxdepthk1 but is significantly faster to train at the expense of a slightly higher training error The parameter maxleafnodes corresponds to the variable Jin the chapter on gradient boosting in F2001 and is related to the parameter interactiondepth in R's gbm package where maxleafnodes = interactiondepth - 1

Mathematical formulation

GBRT considers additive models of the following form

$$f(x) = \sum_{j=1}^J h_j(x)$$

where h_j are the basis functions which are usually called weak learners in the context of boosting Gradient Tree Boosting uses decision trees of fixed size as weak learners Decision trees have a number of abilities that make them valuable for boosting namely the ability to handle data of mixed type and the ability to model complex functions Similar to other boosting algorithms GBRT builds the additive model in a greedy fashion

$$f_m(x) = f_{m-1}(x) + h_m(x)$$

where the newly added tree h_m tries to minimize the loss ℓ given the previous ensemble f_{m-1}

$$h_m = \arg \min$$

$$h \sum_{i=1}^n \ell(y_i - f_{m-1}(x_i) + h(x_i))$$

The initial model f_0 is problem specific for leastsquares regression one usually chooses the mean of the target values

Note The initial model can also be specified via the init argument The passed object has to implement fit and predict

Gradient Boosting attempts to solve this minimization problem numerically via steepest descent The steepest descent direction is the negative gradient of the loss function evaluated at the current model \hat{f}_{m-1} which can be calculated for any differentiable loss function

$$\nabla_{\hat{f}_{m-1}} L(y, \hat{f}_{m-1}) = -\sum_{i=1}^n \eta_i \nabla_{\hat{f}_{m-1}} L(y_i, \hat{f}_{m-1})$$

Where the step length η is chosen using line search

$$\eta = \arg \min_{\eta} L(y, \hat{f}_{m-1} + \eta \nabla_{\hat{f}_{m-1}} L(y, \hat{f}_{m-1}))$$

The algorithms for regression and classification only differ in the concrete loss function used

Loss Functions

The following loss functions are supported and can be specified using the parameter loss

- Regression
 - Least squares ls The natural choice for regression due to its superior computational properties The initial model is given by the mean of the target values
 - Least absolute deviation lad A robust loss function for regression The initial model is given by the median of the target values
 - Huber huber Another robust loss function that combines least squares and least absolute deviation use alpha to control the sensitivity with regards to outliers see F2001 for more details
 - Quantile quantile A loss function for quantile regression Use 0 < alpha < 1 to specify the quantile This loss function can be used to create prediction intervals see Prediction Intervals for Gradient Boosting Regression
- Classification
 - Binomial deviance deviance The negative binomial loglikelihood loss function for binary classification provides probability estimates The initial model is given by the log odds ratio
 - Multinomial deviance deviance The negative multinomial loglikelihood loss function for multi class classification with nclasses mutually exclusive classes It provides probability estimates The initial model is given by the prior probability of each class At each iteration nclasses regression trees have to be constructed which makes GBRT rather inefficient for data sets with a large number of classes
 - Exponential loss exponential The same loss function as AdaBoostClassifier Less robust to mislabeled examples than deviance can only be used for binary classification

Regularization

Shrinkage

F2001 proposed a simple regularization strategy that scales the contribution of each weak learner by a factor η

$$\hat{y} = \sum_{t=1}^T \eta_t h_t(x)$$

The parameter η is also called the learning rate because it scales the step length the gradient descent procedure it can be set via the learningrate parameter

The parameter learningrate strongly interacts with the parameter nestimators the number of weak learners to fit Smaller values of learningrate require larger numbers of weak learners to maintain a constant training error Empirical evidence suggests that small values of learningrate favor better test error HTF2009 recommend to set the learning rate to a small constant eg learningrate = 0.1 and choose nestimators by early stopping For a more detailed discussion of the interaction between learningrate and nestimators see R2007

Subsampling

F1999 proposed stochastic gradient boosting which combines gradient boosting with bootstrap averaging bagging At each iteration the base classifier is trained on a fraction subsample of the available training data The subsample is drawn without replacement A typical value of subsample is 0.5

The figure below illustrates the effect of shrinkage and subsampling on the goodness of fit of the model We can clearly see that shrinkage outperforms no shrinkage Subsampling with shrinkage can further increase the accuracy of the model Subsampling without shrinkage on the other hand does poorly

Another strategy to reduce the variance is by subsampling the features analogous to the random splits in RandomForestClassifier The number of subsampled features can be controlled via the maxfeatures parameter

scikitlearn user guide Release 0213

Note Using a small maxfeatures value can significantly decrease the runtime

Stochastic gradient boosting allows to compute outofbag estimates of the test deviance by computing the improvement in deviance on the examples that are not included in the bootstrap sample ie the outofbag examples The improvements are stored in the attribute oobimprovement oobimprovementi holds the improvement in terms of the loss on the OOB samples if you add the ith stage to the current predictions Outofbag estimates can be used for model selection for example to determine the optimal number of iterations OOB estimates are usually very pessimistic thus we recommend to use crossvalidation instead and only use OOB if crossvalidation is too time consuming

Examples

- Gradient Boosting regularization
- Gradient Boosting OutofBag estimates
- OOB Errors for Random Forests

Interpretation

Individual decision trees can be interpreted easily by simply visualizing the tree structure Gradient boosting models however comprise hundreds of regression trees thus they cannot be easily interpreted by visual inspection of the individual trees Fortunately a number of techniques have been proposed to summarize and interpret gradient boosting models

Feature importance

Often features do not contribute equally to predict the target response in many situations the majority of the features are in fact irrelevant When interpreting a model the first question usually is what are those important features and how do they contributing in predicting the target response

Individual decision trees intrinsically perform feature selection by selecting appropriate split points This information can be used to measure the importance of each feature the basic idea is the more often a feature is used in the split points of a tree the more important that feature is This notion of importance can be extended to decision tree ensembles by simply averaging the feature importance of each tree see Feature importance evaluation for more details

The feature importance scores of a fit gradient boosting model can be accessed via the featureimportances

property

```
from sklearndatasets import makehastie102

Voting Classifier

The idea behind the VotingClassifier is to combine conceptually different machine learning classifiers and use a majority vote or the average predicted probabilities soft vote to predict the class labels Such a classifier can be useful for a set of equally well performing model in order to balance out their individual weaknesses

Majority Class Labels MajorityHard Voting

In majority voting the predicted class label for a particular sample is the class label that represents the majority mode of the class labels predicted by each individual classifier

Eg if the prediction for a given sample is

- classifier 1 class 1
- classifier 2 class 1
- classifier 3 class 2

the VotingClassifier with votinghard would classify the sample as “class 1” based on the majority class label

In the cases of a tie the VotingClassifier will select the class based on the ascending sort order Eg in the following scenario

- classifier 1 class 2
- classifier 2 class 1

the class label 1 will be assigned to the sample

Usage

The following example shows how to fit the majority rule classifier

```
from sklearn import datasets
from sklearn.model_selection import cross_val_score
from sklearn.linear_model import LogisticRegression
from sklearn.naive_bayes import GaussianNB
from sklearn.ensemble import RandomForestClassifier
from sklearn.ensemble import VotingClassifier

iris = datasets.load_iris()
X, y = iris.data[13:], iris.target

clf1 = LogisticRegression(solver='lbfgs', multi_class='multinomial',
                          random_state=1)
clf2 = RandomForestClassifier(n_estimators=50, random_state=1)
clf3 = GaussianNB()
eclf = VotingClassifier(estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)],
                        <=>votinghard)

Accuracy 091 004 naive Bayes
Accuracy 095 004 Ensemble

Weighted Average Probabilities Soft Voting

In contrast to majority voting hard voting soft voting returns the class label as argmax of the sum of predicted probabilities

Specific weights can be assigned to each classifier via the weights parameter When weights are provided the predicted class probabilities for each classifier are collected multiplied by the classifier weight and averaged The final class label is then derived from the class label with the highest average probability

To illustrate this with a simple example let's assume we have 3 classifiers and a 3class classification problems where we assign equal weights to all classifiers w11 w21 w31

The weighted average probabilities for a sample would then be calculated as follows

```
classifier class 1 class 2 class 3
classifier 1 w1 02 w1 05 w1 03
classifier 2 w2 06 w2 03 w2 01
classifier 3 w3 03 w3 04 w3 03
weighted average 037 04 023
```

Here the predicted class label is 2 since it has the highest average probability

The following example illustrates how the decision regions may change when a soft VotingClassifier is used based on an linear Support Vector Machine a Decision Tree and a Knearest neighbor classifier

```

scikitlearn user guide Release 0213

Using the VotingClassifier with GridSearchCV

The VotingClassifier can also be used together with GridSearchCV in order to tune the hyperparameters of the individual estimators

```
from sklearn.model_selection import GridSearchCV
clf1 = LogisticRegressionSolver(bfgs, multi_class='multinomial',
                               random_state=1)
clf2 = RandomForestClassifier(random_state=1)
clf3 = GaussianNB()
eclf = VotingClassifier(estimators=[clf1, clf2, clf3], voting='soft')
params = {'lr': 0.01, 'n_estimators': 20, 'max_depth': 200}
grid = GridSearchCV(estimator=eclf, param_grid=params, cv=5)
grid.fit(X_train, y_train)
```

Usage
In order to predict the class labels based on the predicted class probabilities, scikitlearn estimators in the VotingClassifier must support the predict_proba method

```
eclf = VotingClassifier(estimators=[clf1, clf2, clf3], voting='soft')
```

Optionally, weights can be provided for the individual classifiers

```
eclf = VotingClassifier(estimators=[clf1, clf2, clf3], voting='soft', weights=[2, 5, 1])
```

VotingRegressor

The idea behind the VotingRegressor is to combine conceptually different machine learning regressors and return the average predicted values. Such a regressor can be useful for a set of equally well performing models in order to balance out their individual weaknesses.

The following example shows how to fit the VotingRegressor

```
from sklearn import datasets
from sklearn.ensemble import GradientBoostingRegressor
from sklearn.ensemble import RandomForestRegressor
from sklearn.linear_model import LinearRegression
from sklearn.ensemble import VotingRegressor
```

Loading some example data

```
boston = datasets.load_boston()
```

X = boston.data

y = boston.target

Training classifiers

```
reg1 = GradientBoostingRegressor(random_state=1, n_estimators=10)
```

```
reg2 = RandomForestRegressor(random_state=1, n_estimators=10)
```

```
reg3 = LinearRegression()
```

3112 Multiclass and multilabel algorithms

Warning All classifiers in scikitlearn do multiclass classification outofthebox You don't need to use the

sklearnmulticlass module unless you want to experiment with different multiclass strategies

The sklearnmulticlass module implements metaestimators to solvemulticlass andmultilabel clas

sification problems by decomposing such problems into binary classification problems Multitarget regression is also supported

- Multiclass classification means a classification task with more than two classes eg classify a set of images of fruits which may be oranges apples or pears Multiclass classification makes the assumption that each sample is assigned to one and only one label a fruit can be either an apple or a pear but not both at the same time

- Multilabel classification assigns to each sample a set of target labels This can be thought as predicting proper ties of a datapoint that are not mutually exclusive such as topics that are relevant for a document A text might be about any of religion politics finance or education at the same time or none of these

- Multioutput regression assigns each sample a set of target values This can be thought of as predicting several properties for each datapoint such as wind direction and magnitude at a certain location

31 Supervised learning 307

scikitlearn user guide Release 0213

•Multioutputmulticlass classification andmultitask classification means that a single estimator has to handle several joint classification tasks This is both a generalization of the multilabel classification task which only considers binary classification as well as a generalization of the multiclass classification task The output format is a 2d numpy array or sparse matrix

The set of labels can be different for each output variable For instance a sample could be assigned “pear” for an output variable that takes possible values in a finite set of species such as “pear” “apple” and “blue” or “green” for a second output variable that takes possible values in a finite set of colors such as “green” “red” “blue” “yellow”

This means that any classifiers handling multioutput multiclass or multitask classification tasks support the multilabel classification task as a special case Multitask classification is similar to the multioutput classification task with different model formulations For more information see the relevant estimator documentation All scikitlearn classifiers are capable of multiclass classification but the metaestimators offered by sklearn multiclass permit changing the way they handle more than two classes because this may have an effect on classifier performance either in terms of generalization error or required computational resources Below is a summary of the classifiers supported by scikitlearn grouped by strategy you don’t need the metaestimators in this class if you’re using one of these unless you want custom multiclass behavior

Warning At present no metric in sklearnmetrics supports the multioutputmulticlass classification task

Multilabel classification format

In multilabel learning the joint set of binary classification tasks is expressed with label binary indicator array each sample is one row of a 2d array of shape nsamples nclasses with binary values the one ie the non zero elements corresponds to the subset of labels An array such as nparray1 0 0 0 1 1 0 0 0

represents label 0 in the first sample labels 1 and 2 in the second sample and no labels in the third sample

Producing multilabel data as a list of sets of labels may be more intuitive The MultiLabelBinarizer transformer

can be used to convert between a collection of collections of labels and the indicator format

31 Supervised learning 309

Multioutput regression

Multioutput regression support can be added to any regressor with MultiOutputRegressor. This strategy consists of fitting one regressor per target. Since each target is represented by exactly one regressor, it is possible to gain knowledge about the target by inspecting its corresponding regressor. As MultiOutputRegressor fits one regressor per target, it can not take advantage of correlations between targets.

Below is an example of multioutput regression:

```
from sklearn.datasets import make_regression
from sklearn.multioutput import MultiOutputRegressor
from sklearn.ensemble import GradientBoostingRegressor
X, y = make_regression(n_samples=10, n_targets=3, random_state=1)
MultiOutputRegressor(GradientBoostingRegressor()).fit(X, y)
#> predict(X)
array([15475474165, 14703498585, 5003812219,
       712165031, 512914884, 8146081961,
       1878948621, 10044373091, 1388978285,
       14162745778, 9502891072, 19148204257,
       9703260883, 16534867495, 13952003279,
       12392529176, 2125719016, 784253,
       12225193977, 8516443186, 10712274212,
       30170388, 9480956739, 1216979946,
       14072667194, 17650941682, 1750447799,
       14937967282, 8115699552, 572850319])
```

Multioutput classification

Multioutput classification support can be added to any classifier with MultiOutputClassifier. This strategy consists of fitting one classifier per target. This allows multiple target variable classifications. The purpose of this class is to extend estimators to be able to estimate a series of target functions $f_1, f_2, f_3, \dots, f_n$ that are trained on a single X predictor matrix to predict a series of responses $y_1, y_2, y_3, \dots, y_n$.

Below is an example of multioutput classification:

```
from sklearn.datasets import make_classification
from sklearn.multioutput import MultiOutputClassifier
from sklearn.ensemble import RandomForestClassifier
from sklearn.utils import shuffle
import numpy as np
X, y1 = make_classification(n_samples=10, n_features=100, n_informative=30, n
#> classes=3, random_state=1)
y2 = shuffle(y1, random_state=1)
y3 = shuffle(y1, random_state=2)
Y = np.vstack((y1, y2, y3))
n_samples, n_features = X.shape
n_outputs = Y.shape[1]
n_classes = 3
forest = RandomForestClassifier(n_estimators=100, random_state=1)
MultiOutputClassifier(forest).fit(X, Y)
```

Classifier Chain

Classifier chains see ClassifierChain are a way of combining a number of binary classifiers into a single multilabel model that is capable of exploiting correlations among targets

For a multilabel classification problem with N classes N binary classifiers are assigned an integer between 0 and N1

These integers define the order of models in the chain Each classifier is then fit on the available training data plus the true labels of the classes whose models were assigned a lower number

When predicting the true labels will not be available Instead the predictions of each model are passed on to the subsequent models in the chain to be used as features

Clearly the order of the chain is important The first model in the chain has no information about the other labels while the last model in the chain has features indicating the presence of all of the other labels In general one does not know the optimal ordering of the models in the chain so typically many randomly ordered chains are fit and their predictions are averaged together

References

Jesse Read Bernhard Pfahringer Geoff Holmes Eibe Frank “Classifier Chains for Multilabel Classification” 2009

Regressor Chain

Regressor chains see RegressorChain is analogous to ClassifierChain as a way of combining a number of regressions into a single multitarget model that is capable of exploiting correlations among targets

3113 Feature selection

The classes in the sklearnfeatureselection module can be used for feature selectiondimensionality reduction on sample sets either to improve estimators’ accuracy scores or to boost their performance on very high dimensional datasets

Removing features with low variance

VarianceThreshold is a simple baseline approach to feature selection It removes all features whose variance doesn’t meet some threshold By default it removes all zero variance features ie features that have the same value in all samples

scikitlearn user guide Release 0213

As an example suppose that we have a dataset with boolean features and we want to remove all features that are either one or zero on or off in more than 80 of the samples Boolean features are Bernoulli random variables and the variance of such variables is given by

```
Var = p(1-p)
so we can select using the threshold 81 / 8
from sklearn.feature_selection import VarianceThreshold
X = [[0, 0, 1, 0, 1, 0, 1, 0, 0, 0, 1, 1, 0, 1, 0, 0, 1, 1]
sel = VarianceThreshold(threshold=0.8)
sel.fit_transform(X)
array([[0, 1,
        1, 0,
        0, 0,
        1, 1,
        1, 0,
        1, 1]
```

As expected VarianceThreshold has removed the first column which has a probability of 56.8% of containing a zero

Univariate feature selection

Univariate feature selection works by selecting the best features based on univariate statistical tests It can be seen as a preprocessing step to an estimator Scikitlearn exposes feature selection routines as objects that implement the transform method

- SelectKBest removes all but the k highest scoring features
- SelectPercentile removes all but a user specified highest scoring percentage of features
- using common univariate statistical tests for each feature false positive rate SelectFpr false discovery rate SelectFdr or family wise error SelectFwe
- GenericUnivariateSelect allows to perform univariate feature selection with a configurable strategy This allows to select the best univariate selection strategy with hyperparameter search estimator

For instance we can perform a chi2 test to the samples to retrieve only the two best features as follows

```
from sklearn.datasets import load_iris
from sklearn.feature_selection import SelectKBest
from sklearn.feature_selection import chi2
iris = load_iris()
X, y = iris.data, iris.target
X.shape
(150, 4)
X_new = SelectKBest(chi2, k=2).fit_transform(X, y)
X_new.shape
(150, 2)
```

These objects take as input a scoring function that returns univariate scores and p-values or only scores for

- SelectKBest and SelectPercentile
- For regression f_regression mutual_info_regression
- For classification chi2 f_classif mutual_info_classif

scikitlearn user guide Release 0213

The methods based on Ftest estimate the degree of linear dependency between two random variables On the other hand mutual information methods can capture any kind of statistical dependency but being nonparametric they require more samples for accurate estimation

Feature selection with sparse data

If you use sparse data ie data represented as sparse matrices chi2 mutualinfo regression

mutualinfoclassif will deal with the data without making it dense

Warning Beware not to use a regression scoring function with a classification problem you will get useless results

Examples

- Univariate Feature Selection
 - Comparison of Ftest and mutual information
- Recursive feature elimination

Given an external estimator that assigns weights to features eg the coefficients of a linear model recursive feature elimination RFE is to select features by recursively considering smaller and smaller sets of features First the estimator is trained on the initial set of features and the importance of each feature is obtained either through a coef attribute or through a featureimportances attribute Then the least important features are pruned from current set of features That procedure is recursively repeated on the pruned set until the desired number of features to select is eventually reached

RFECV performs RFE in a crossvalidation loop to find the optimal number of features

Examples

- Recursive feature elimination A recursive feature elimination example showing the relevance of pixels in a digit classification task
- Recursive feature elimination with crossvalidation A recursive feature elimination example with automatic tuning of the number of features selected with crossvalidation

Feature selection using SelectFromModel

SelectFromModel is a metatransformer that can be used along with any estimator that has a coef or featureimportances attribute after fitting The features are considered unimportant and removed if the corresponding coef or featureimportances values are below the provided threshold parameter Apart from specifying the threshold numerically there are builtin heuristics for finding a threshold using a string argument Available heuristics are “mean” “median” and float multiples of these like “01mean”

For examples on how it is to be used refer to the sections below

316 Chapter 3 User Guide

scikitlearn user guide Release 0213

Examples

•Feature selection using SelectFromModel and LassoCV Selecting the two most important features from the Boston dataset without knowing the threshold beforehand

L1based feature selection

Linear models penalized with the L1 norm have sparse solutions many of their estimated coefficients are zero When the goal is to reduce the dimensionality of the data to use with another classifier they can be used along withfeatureselectionSelectFromModel to select the nonzero coefficients In particular sparse estimators useful for this purpose are the linearmodelLasso for regression and of linearmodel

LogisticRegression andsvmLinearSVC for classification

```
from sklearnsvm import LinearSVC
from sklearndatasets import loadiris
from sklearnfeatureselection import SelectFromModel
```

```
iris = loadiris
X, y = iris.data, iris.target
X.shape
150, 4
```

```
lsvc = LinearSVCC001 penaltyl1 dual FalsefitX, y
model = SelectFromModel(lsvc, prefit=True)
```

```
X_new = model.transform(X)
X_new.shape
150, 3
```

With SVMs and logisticregression the parameter C controls the sparsity the smaller C the fewer features selected With Lasso the higher the alpha parameter the fewer features selected

Examples

•Classification of text documents using sparse features Comparison of different algorithms for document classification including L1based feature selection

L1recovery and compressive sensing

For a good choice of alpha the Lasso can fully recover the exact set of nonzero variables using only few observations provided certain specific conditions are met In particular the number of samples should be “sufficiently large” or L1 models will perform at random where “sufficiently large” depends on the number of nonzero coefficients the logarithm of the number of features the amount of noise the smallest absolute value of nonzero coefficients and the structure of the design matrix X In addition the design matrix must display certain specific properties such as not being too correlated

There is no general rule to select an alpha parameter for recovery of nonzero coefficients It can be set by cross validation LassoCV orLassoLarsCV though this may lead to underpenalized models including a small number of nonrelevant variables is not detrimental to prediction score BIC LassoLarsIC tends on the opposite to set high values of alpha

31 Supervised learning 317

scikitlearn user guide Release 0213

Treebased feature selection

Treebased estimators see the sklearnntree module and forest of trees in the sklearnensemble module can be used to compute feature importances which in turn can be used to discard irrelevant features when coupled with thesklearnfeatureselectionSelectFromModel metatransformer

```
from sklearnensemble import ExtraTreesClassifier
from sklearnndatasets import loadiris
from sklearnfeatureselection import SelectFromModel
iris = loadiris
```

```
X, y = iris.data, iris.target
X.shape
(150, 4)
clf = ExtraTreesClassifier(n_estimators=50)
clf.fit(X, y)
clf.feature_importances_
array([0.04, 0.05, 0.4, 0.4])
model = SelectFromModel(clf, prefit=True)
X_new = model.transform(X)
X_new.shape
(150, 2)
```

- Examples
- Feature importances with forests of trees example on synthetic data showing the recovery of the actually meaningful features
 - Pixel importances with a parallel forest of trees example on face recognition data

Feature selection as part of a pipeline

Feature selection is usually used as a preprocessing step before doing the actual learning The recommended way to do this in scikitlearn is to use a sklearnpipelinePipeline

```
clf = Pipeline([
    ('featureselection', SelectFromModel(LinearSVC(penalty=l1))),
    ('classification', RandomForestClassifier())])
```

clf.fit(X, y)

In this snippet we make use of a sklearnsvmLinearSVC coupled with sklearnfeatureselection SelectFromModel to evaluate feature importances and select the most relevant features Then a sklearn ensembleRandomForestClassifier is trained on the transformed output ie using only relevant features

You can perform similar operations with the other feature selection methods and also classifiers that provide a way to evaluate feature importances of course See the sklearnpipelinePipeline examples for more details

3114 SemiSupervised

Semisupervised learning is a situation in which in your training data some of the samples are not labeled The semi supervised estimators in sklearnsemisupervised are able to make use of this additional unlabeled data to better capture the shape of the underlying data distribution and generalize better to new samples These algorithms can perform well when we have a very small amount of labeled points and a large amount of unlabeled points

Unlabeled entries in y

It is important to assign an identifier to unlabeled points along with the labeled data when training the model with thefit method The identifier that this implementation uses is the integer value -1

Label Propagation

Label propagation denotes a few variations of semisupervised graph inference algorithms

A few features available in this model

- Can be used for classification and regression tasks
- Kernel methods to project data into alternate dimensional spaces

scikitlearn provides two label propagation models LabelPropagation andLabelSpreading Both work by constructing a similarity graph over all items in the input dataset

Fig 31 An illustration of labelpropagation the structure of unlabeled observations is consistent with the class structure and thus the class label can be propagated to the unlabeled observations of the training set LabelPropagation andLabelSpreading differ in modifications to the similarity matrix that graph and the clamping effect on the label distributions Clamping allows the algorithm to change the weight of the true ground labeled data to some degree The LabelPropagation algorithm performs hard clamping of input labels which means $\gamma = 0$ This clamping factor can be relaxed to say $\gamma = 0.2$ which means that we will always retain 80 percent of our original label distribution but the algorithm gets to change its confidence of the distribution within 20 percent LabelPropagation uses the raw similarity matrix constructed from the data with no modifications In contrast LabelSpreading minimizes a loss function that has regularization properties as such it is often more robust to noise The algorithm iterates on a modified version of the original graph and normalizes the edge weights by computing the normalized graph Laplacian matrix This procedure is also used in Spectral clustering Label propagation models have two builtin kernel methods Choice of kernel effects both scalability and performance of the algorithms The following are available

- rbf $\exp(-\gamma \|x - x'\|^2)$ γ is specified by keyword gamma
- knn $\frac{1}{\|x - x'\|}$ γ is specified by keyword nneighbors

31 Supervised learning 319

scikitlearn user guide Release 0213

The RBF (Radial Basis Function) kernel will produce a fully connected graph which is represented in memory by a dense matrix This matrix may be very large and combined with the cost of performing a full matrix multiplication calculation for each iteration of the algorithm can lead to prohibitively long running times On the other hand the KNN kernel will produce a much more memoryfriendly sparse matrix which can drastically reduce running times

Examples

- Decision boundary of label propagation versus SVM (Support Vector Machine) on the Iris dataset
- Label Propagation learning a complex structure
- Label Propagation digits Demonstrating performance
- Label Propagation digits active learning

3115 Isotonic regression

The classIsotonicRegression fits a nondecreasing function to data It solves the following problem

minimize \sum

$\sum_{i=1}^n (y_i - \hat{y}_i)^2$

subject to $\hat{y}_1 \leq \hat{y}_2 \leq \dots \leq \hat{y}_n$

where each y_i is strictly positive and each \hat{y}_i is an arbitrary real number It yields the vector which is composed of nondecreasing elements the closest in terms of mean squared error In practice this list of elements forms a function that is piecewise linear

3116 Probability calibration

When performing classification you often want not only to predict the class label but also obtain a probability of the respective label This probability gives you some kind of confidence on the prediction Some models can give you poor estimates of the class probabilities and some even do not support probability prediction The calibration module allows you to better calibrate the probabilities of a given model or to add support for probability prediction Well calibrated classifiers are probabilistic classifiers for which the output of the predict_proba method can be directly interpreted as a confidence level For instance a well calibrated binary classifier should classify the samples such that among the samples to which it gave a predict_proba value close to 0.8 approximately 80 actually belong to the positive class The following plot compares how well the probabilistic predictions of different classifiers are calibrated LogisticRegression returns well calibrated predictions by default as it directly optimizes logloss In contrast the other methods return biased probabilities with different biases per method

- GaussianNB tends to push probabilities to 0 or 1 note the counts in the histograms This is mainly because it makes the assumption that features are conditionally independent given the class which is not the case in this dataset which contains 2 redundant features

scikitlearn user guide Release 0213

•RandomForestClassifier shows the opposite behavior the histograms show peaks at approximately 0.2 and 0.9 probability while probabilities close to 0 or 1 are very rare An explanation for this is given by NiculescuMizil and Caruana4 “Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values Because predictions are restricted to the interval [0,1] errors caused by variance tend to be onesided near zero and one For example if a model should predict p = 0 for a case the only way bagging can achieve this is if all bagged trees predict zero If we add noise to the trees that bagging is averaging over this noise will cause some trees to predict values larger than 0 for this case thus moving the average prediction of the bagged ensemble away from 0 We observe this effect most strongly with random forests because the baselevel trees trained with random forests have relatively high variance due to feature subsetting” As a result the calibration curve also referred to as the reliability diagram Wilks 19955 shows a characteristic sigmoid shape indicating that the classifier could trust its “intuition” more and return probabilities closer to 0 or 1 typically

• Linear Support Vector Classification LinearSVC shows an even more sigmoid curve as the RandomForest Classifier which is typical for maximummargin methods compare NiculescuMizil and Caruana4 which focus on hard samples that are close to the decision boundary the support vectors

Two approaches for performing calibration of probabilistic predictions are provided a parametric approach based on Platt’s sigmoid model and a nonparametric approach based on isotonic regression sklearnisotonic Probability calibration should be done on new data not used for model fitting The class CalibratedClassifierCV uses a crossvalidation generator and estimates for each split the model parameter on the train samples and the calibration of the test samples The probabilities predicted for the folds are then averaged Already fitted classifiers can be calibrated by CalibratedClassifierCV via the parameter cv=”prefit” In this case the user has to take care manually that data for model fitting and calibration are disjoint

The following images demonstrate the benefit of probability calibration The first image present a dataset with 2 classes and 3 blobs of data The blob in the middle contains random samples of each class The probability for the samples in this blob should be 0.5

The following image shows on the data above the estimated probability using a Gaussian naive Bayes classifier without calibration with a sigmoid calibration and with a nonparametric isotonic calibration One can observe that the non parametric model provides the most accurate probability estimates for samples in the middle ie 0.5

The following experiment is performed on an artificial dataset for binary classification with 100000 samples 1000 of them are used for model fitting with 20 features Of the 20 features only 2 are informative and 10 are redundant The figure shows the estimated probabilities obtained with logistic regression a linear supportvector classifier SVC (Support Vector Classification) and linear SVC (Support Vector Classification) with both isotonic calibration and sigmoid calibration The Brier score is a metric which is a combination of calibration loss and refinement loss brierscoreloss reported in the legend the smaller the better Calibration loss is defined as the mean squared deviation from empirical probabilities derived from the slope of ROC segments Refinement loss can be defined as the expected optimal loss as measured by the area under the optimal cost curve

One can observe here that logistic regression is well calibrated as its curve is nearly diagonal Linear SVC (Support Vector Classification)’s calibration curve or reliability diagram has a sigmoid curve which is typical for an underconfident classifier In the case of LinearSVC this is caused by the margin property of the hinge loss which lets the model focus on hard samples that are close to the decision boundary the support vectors Both kinds of calibration can fix this issue and yield nearly identical results The next figure shows the calibration curve of Gaussian naive Bayes on the same data with both kinds of calibration and also without calibration

One can see that Gaussian naive Bayes performs very badly but does so in an other way than linear SVC (Support Vector Classification) While linear SVC (Support Vector Classification) exhibited a sigmoid calibration curve Gaussian naive Bayes’ calibration curve has a transposedsigmoid shape This is typical for an overconfident classifier In this case the classifier’s overconfidence is caused by the redundant features which violate the naive Bayes assumption of featureindependence

4Predicting Good Probabilities with Supervised Learning A NiculescuMizil R Caruana ICML 2005

5On the combination of forecast probabilities for consecutive precipitation periods Wea Forecasting 5 640–650 Wilks D S 1990a

31 Supervised learning 323

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve Sigmoid calibration also improves the brier score slightly albeit not as strongly as the nonparametric isotonic calibration This is an intrinsic limitation of sigmoid calibration whose parametric form assumes a sigmoid rather than a transposedsigmoid curve The nonparametric isotonic calibration model however makes no such strong assumptions and can deal with either shape provided that there is sufficient calibration data In general sigmoid calibration is preferable in cases where the calibration curve is sigmoid and where there is limited calibration data while isotonic calibration is preferable for nonsigmoid calibration curves and in situations where large amounts of data are available for calibration

CalibratedClassifierCV can also deal with classification tasks that involve more than two classes if the base estimator can do so In this case the classifier is calibrated first for each class separately in an onevsrest fashion When predicting probabilities for unseen data the calibrated probabilities for each class are predicted separately As those probabilities do not necessarily sum to one a postprocessing is performed to normalize them The next image illustrates how sigmoid calibration changes predicted probabilities for a 3class classification problem Illustrated is the standard 2simplex where the three corners correspond to the three classes Arrows point from the probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a holdout validation set Colors indicate the true class of an instance red class 1 green class 2 blue class 3

The base classifier is a random forest classifier with 25 base estimators trees If this classifier is trained on all 800 training datapoints it is overly confident in its predictions and thus incurs a large logloss Calibrating an identical classifier which was trained on 600 datapoints with method'sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions ie moves the probability vectors from the edges of the simplex towards the center

scikitlearn user guide Release 0213

This calibration results in a lower logloss Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in logloss

3117 Neural network models supervised

Warning This implementation is not intended for largescale applications In particular scikitlearn offers no GPU support For much faster GPUbased implementations as well as frameworks offering much more flexibility to build deep learning architectures see Related Projects

Multilayer Perceptron

Multilayer Perceptron MLP is a supervised learning algorithm that learns a function $f: \mathbb{R}^n \rightarrow \mathbb{R}^m$ by training on a dataset where n is the number of dimensions for input and m is the number of dimensions for output Given a set of features x_1, x_2, \dots, x_n and a target y it can learn a nonlinear function approximator for either classification or regression It is different from logistic regression in that between the input and the output layer there can be one or more nonlinear layers called hidden layers Figure 1 shows a one hidden layer MLP with scalar output

Fig 32 Figure 1 One hidden layer MLP

The leftmost layer known as the input layer consists of a set of neurons x_1, x_2, \dots, x_n representing the input features Each neuron in the hidden layer transforms the values from the previous layer with a weighted linear summation $w_1x_1 + w_2x_2 + \dots + w_nx_n$ followed by a nonlinear activation function $f: \mathbb{R} \rightarrow \mathbb{R}$ like the hyperbolic tan function The output layer receives the values from the last hidden layer and transforms them into output values

scikitlearn user guide Release 0213

The module contains the public attributes `coefs` and `intercepts` `coefs` is a list of weight matrices where weight matrix at index `i` represents the weights between layer `i` and layer `i+1` `intercepts` is a list of bias vectors where the vector at index `i` represents the bias values added to layer `i`

The advantages of Multilayer Perceptron are

- Capability to learn nonlinear models
- Capability to learn models in realtime online learning using `partialfit`

The disadvantages of Multilayer Perceptron MLP include

- MLP with hidden layers have a nonconvex loss function where there exists more than one local minimum Therefore different random weight initializations can lead to different validation accuracy
- MLP requires tuning a number of hyperparameters such as the number of hidden neurons layers and iterations
- MLP is sensitive to feature scaling

Please see Tips on Practical Use section that addresses some of these disadvantages

Classification

`ClassMLPClassifier` implements a multilayer perceptron MLP algorithm that trains using Backpropagation MLP trains on two arrays `array X` of size `nsamples nfeatures` which holds the training samples represented as floating point feature vectors and `array y` of size `nsamples` which holds the target values class labels for the training samples

```
from sklearn.neuralnetwork import MLPClassifier
```

```
X = [[0, 0, 1, 1],
```

```
     [0, 1, 0, 1]]
```

```
y = [0, 1]
```

```
clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
```

```
                   hidden_layer_sizes=(5, 2), random_state=1)
```

```
clf.fit(X, y)
```

```
MLPClassifier(activation=relu, alpha=1e-05, batch_size=auto,
```

```
beta=109, beta_2=0.999, early_stopping=False,
```

```
epsilon=1e-08, hidden_layer_sizes=(5, 2),
```

```
learning_rate=constant, learning_rate_init=0.001,
```

```
max_iter=200, momentum=0.9, n_iter_no_change=10,
```

```
nesterovs_momentum=True, power_t=0.5, random_state=1,
```

```
shuffle=True, solver='lbfgs', tol=0.0001,
```

```
validation_fraction=0.1, verbose=False, warm_start=False)
```

After fitting training the model can predict labels for new samples

```
clf.predict([[2, 2, 1, 2],
```

```
            [1, 0]])
```

MLP can fit a nonlinear model to the training data `clf.coefs` contains the weight matrices that constitute the model parameters

```
coef_shape = [coefs[i].shape for i in range(len(coefs))]
```

```
[2, 5, 5, 2, 2, 1]
```

Currently `MLPClassifier` supports only the CrossEntropy loss function which allows probability estimates by running the `predict_proba` method

31 Supervised learning 331

scikitlearn user guide Release 0213

MLP trains using Backpropagation More precisely it trains using some form of gradient descent and the gradients are calculated using Backpropagation For classification it minimizes the CrossEntropy loss function giving a vector of probability estimates [] per sample []

```
clf.predict_proba(2, 1, 2)
array([1.967e+04, 9.998e+01,
       1.967e+04, 9.998e+01])
```

MLPClassifier supports multiclass classification by applying Softmax as the output function Further the model supports multilabel classification in which a sample can belong to more than one class For each class the raw output passes through the logistic function Values larger or equal to 0.5 are rounded to 1 otherwise to 0 For a predicted output of a sample the indices where the value is 1 represents the assigned classes of that sample

```
X = [[0, 1, 1],
     [0, 1, 1],
     [0, 1, 1]]
y = [0, 1, 1, 1]
clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
                   hidden_layer_sizes=(15, ), random_state=1)
```

```
clf.fit(X, y)
MLPClassifier(activation=relu, alpha=1e-05, batch_size='auto',
              beta_1=0.9, beta_2=0.999, early_stopping=False,
              epsilon=1e-08, hidden_layer_sizes=(15, ),
              learning_rate='constant', learning_rate_init=0.001,
              max_iter=200, momentum=0.9, n_iter_no_change=10,
              nesterovs_momentum=True, power_t=0.5, random_state=1,
              shuffle=True, solver='lbfgs', tol=0.0001,
              validation_fraction=0.1, verbose=False, warm_start=False)
clf.predict(1, 2)
array([1, 1])
clf.predict(0, 0)
array([0, 1])
```

See the examples below and the docstring of MLPClassifier.fit for further information

Examples

- Compare Stochastic learning strategies for MLPClassifier
- Visualization of MLP weights on MNIST

Regression

ClassMLPRegressor implements a multilayer perceptron MLP that trains using backpropagation with no activation function in the output layer which can also be seen as using the identity function as activation function Therefore it uses the square error as the loss function and the output is a set of continuous values

MLPRegressor also supports multioutput regression in which a sample can have more than one target

Regularization

BothMLPRegressor andMLPClassifier use parameter alpha for regularization L2 regularization term which helps in avoiding overfitting by penalizing weights with large magnitudes Following plot displays varying decision function with value of alpha

scikitlearn user guide Release 0213
See the examples below for further information
Examples
•Varying regularization in Multilayer Perceptron

Algorithms
MLP trains using Stochastic Gradient Descent Adam or LBFGS Stochastic Gradient Descent SGD updates pa
rameters using the gradient of the loss function with respect to a parameter that needs adaptation ie
 $\theta \leftarrow \theta - \eta \nabla_{\theta} L(\theta)$
where η is the learning rate which controls the stepsize in the parameter space search $L(\theta)$ is the loss function used
for the network

More details can be found in the documentation of SGD
Adam is similar to SGD in a sense that it is a stochastic optimizer but it can automatically adjust the amount to update
parameters based on adaptive estimates of lowerorder moments
With SGD or Adam training supports online and minibatch learning
LBFGS is a solver that approximates the Hessian matrix which represents the secondorder partial derivative of a
function Further it approximates the inverse of the Hessian matrix to perform parameter updates The implementation
uses the Scipy version of LBFGS
If the selected solver is 'LBFGS' training does not support online nor minibatch learning
31 Supervised learning 333

Complexity

Suppose there are n training samples m features h hidden layers each containing h neurons for simplicity and o output neurons The time complexity of backpropagation is $O(n \cdot m \cdot h \cdot o \cdot i)$ where i is the number of iterations Since backpropagation has a high time complexity it is advisable to start with smaller number of hidden neurons and few hidden layers for training

Mathematical formulation

Given a set of training examples x_1, x_2, \dots, x_n where $x_i \in \mathbb{R}^m$ and $y_i \in \{0, 1\}$ a one hidden layer one hidden neuron MLP learns the function $f(x) = \sigma(w_1 x + b_1)$

where $w_1 \in \mathbb{R}^{m \times h}$ and $b_1 \in \mathbb{R}^h$ are model parameters w_1 and b_1 represent the weights of the input layer and hidden layer respectively and $w_2 \in \mathbb{R}^{h \times o}$ and $b_2 \in \mathbb{R}^o$ represent the bias added to the hidden layer and the output layer respectively $\sigma: \mathbb{R} \rightarrow \mathbb{R}$ is the activation function set by default as the hyperbolic tan It is given as

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

For binary classification $\sigma(x)$ passes through the logistic function $\sigma(x) = \frac{1}{1 + e^{-x}}$ to obtain output values between zero and one A threshold set to 0.5 would assign samples of outputs larger or equal 0.5 to the positive class and the rest to the negative class

If there are more than two classes $\sigma(x)$ itself would be a vector of size $n_{classes}$ Instead of passing through logistic function it passes through the softmax function which is written as

$$\text{softmax}(x) = \frac{\exp(x_i)}{\sum_j \exp(x_j)}$$

where x_i represents the i th element of the input to softmax which corresponds to class i and n is the number of classes The result is a vector containing the probabilities that sample x belong to each class The output is the class with the highest probability

In regression the output remains as $\sigma(x)$ therefore output activation function is just the identity function

MLP uses different loss functions depending on the problem type The loss function for classification is CrossEntropy which in binary case is given as

$$L = -\frac{1}{n} \sum_{i=1}^n [y_i \ln \sigma(x_i) + (1 - y_i) \ln (1 - \sigma(x_i))]$$

where n is

λ is an L2 regularization term aka penalty that penalizes complex models and $\lambda \geq 0$ is a nonnegative hyperparameter that controls the magnitude of the penalty

For regression MLP uses the Square Error loss function written as

$$L = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$$

Starting from initial random weights multilayer perceptron MLP minimizes the loss function by repeatedly updating these weights After computing the loss a backward pass propagates it from the output layer to the previous layers providing each weight parameter with an update value meant to decrease the loss

In gradient descent the gradient $\nabla_{w_j} L$ of the loss with respect to the weights is computed and deducted from w_j More formally this is expressed as

$$w_j = w_j - \eta \nabla_{w_j} L$$

where j is the iteration step and η is the learning rate with a value larger than 0

The algorithm stops when it reaches a preset maximum number of iterations or when the improvement in loss is below a certain small number

scikitlearn user guide Release 0213

Tips on Practical Use

- Multilayer Perceptron is sensitive to feature scaling so it is highly recommended to scale your data For example scale each attribute on the input vector X to 0 1 or 1 1 or standardize it to have mean 0 and variance 1 Note that you must apply the same scaling to the test set for meaningful results You can use StandardScaler for standardization

```
from sklearn.preprocessing import StandardScaler
scaler = StandardScaler
```

Dont cheat fit only on training data

```
scaler.fit(Xtrain)
```

```
Xtrain = scaler.transform(Xtrain)
```

apply same transformation to test data

```
Xtest = scaler.transform(Xtest)
```

An alternative and recommended approach is to use StandardScaler in a Pipeline

- Finding a reasonable regularization parameter λ is best done using GridSearchCV usually in the range 100 nparange1 7

- Empirically we observed that LBFGS converges faster and with better solutions on small datasets For relatively large datasets however Adam is very robust It usually converges quickly and gives pretty good performance Stochastic Gradient Descent with momentum or nesterov’s momentum on the other hand can perform better than those two algorithms if learning rate is correctly tuned

More control with warmstart

If you want more control over stopping criteria or learning rate in SGD or want to do additional monitoring using warmstart=True and max_iter=1 and iterating yourself can be helpful

```
X = [[0, 0, 1, 1],
     [0, 1, 0, 1]]
y = [0, 1]
clf = MLPClassifier(hidden_layer_sizes=(15, ), random_state=1, max_iter=1, warm
                    start=True)
for i in range(10):
    clf.fit(X, y)
    # additional monitoring / inspection
MLPClassifier
```

32 Unsupervised learning

321 Gaussian mixture models

sklearnmixture is a package which enables one to learn Gaussian Mixture Models diagonal spherical tied and full covariance matrices supported sample them and estimate them from data Facilities to help determine the appropriate number of components are also provided

Fig 33 Twocomponent Gaussian mixture model data points and equiprobability surfaces of the model

A Gaussian mixture model is a probabilistic model that assumes all the data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters One can think of mixture models as generalizing kmeans clustering to incorporate information about the covariance structure of the data as well as the centers of the latent Gaussians

Scikitlearn implements different classes to estimate Gaussian mixture models that correspond to different estimation strategies detailed below

Gaussian Mixture

TheGaussianMixture object implements the expectationmaximization EM algorithm for fitting mixtureof Gaussian models It can also draw confidence ellipsoids for multivariate models and compute the Bayesian Infor mation Criterion to assess the number of clusters in the data A GaussianMixturefit method is provided that learns a Gaussian Mixture Model from train data Given test data it can assign to each sample the Gaussian it mostly probably belong to using the GaussianMixturepredict method

TheGaussianMixture comes with different options to constrain the covariance of the difference classes estimated spherical diagonal tied or full covariance

Examples

- See GMM covariances for an example of using the Gaussian mixture as clustering on the iris dataset
- See Density Estimation for a Gaussian mixture for an example on plotting the density estimation

scikitlearn user guide Release 0213

Pros and cons of class GaussianMixture

Pros

Speed It is the fastest algorithm for learning mixture models

Agnostic As this algorithm maximizes only the likelihood it will not bias the means towards zero or bias the cluster sizes to have specific structures that might or might not apply

Cons

Singularities When one has insufficiently many points per mixture estimating the covariance matrices becomes difficult and the algorithm is known to diverge and find solutions with infinite likelihood unless one regularizes the covariances artificially

Number of components This algorithm will always use all the components it has access to needing heldout data or information theoretical criteria to decide how many components to use in the absence of external cues

Selecting the number of components in a classical Gaussian Mixture Model

The BIC criterion can be used to select the number of components in a Gaussian Mixture in an efficient way In theory it recovers the true number of components only in the asymptotic regime ie if much data is available and assuming

32 Unsupervised learning 337

scikitlearn user guide Release 0213

that the data was actually generated iid from a mixture of Gaussian distribution Note that using a Variational Bayesian Gaussian mixture avoids the specification of the number of components for a Gaussian mixture model

Examples

- See Gaussian Mixture Model Selection for an example of model selection performed with classical Gaussian mixture

Estimation algorithm Expectationmaximization

The main difficulty in learning Gaussian mixture models from unlabeled data is that it is one usually doesn't know which points came from which latent component if one has access to this information it gets very easy to fit a separate Gaussian distribution to each set of points Expectationmaximization is a wellfounded statistical algorithm to get around this problem by an iterative process First one assumes random components randomly centered on data points learned from kmeans or even just normally distributed around the origin and computes for each point a probability of being generated by each component of the model Then one tweaks the parameters to maximize the likelihood of the data given those assignments Repeating this process is guaranteed to always converge to a local optimum

Variational Bayesian Gaussian Mixture

TheBayesianGaussianMixture object implements a variant of the Gaussian mixture model with variational inference algorithms The API (Application Programming Interface) is similar as the one defined by GaussianMixture Estimation algorithm variational inference

Variational inference is an extension of expectationmaximization that maximizes a lower bound on model evidence including priors instead of data likelihood The principle behind variational methods is the same as expectation maximization that is both are iterative algorithms that alternate between finding the probabilities for each point to

be generated by each mixture and fitting the mixture to these assigned points but variational methods add regularization by integrating information from prior distributions This avoids the singularities often found in expectation maximization solutions but introduces some subtle biases to the model Inference is often notably slower but not usually as much so as to render usage unpractical

Due to its Bayesian nature the variational algorithm needs more hyper parameters than expectation maximization the most important of these being the concentration parameter `weightconcentrationprior` Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero High values of the concentration prior will allow a larger number of components to be active in the mixture

The parameters implementation of the `BayesianGaussianMixture` class proposes two types of prior for the weights distribution a finite mixture model with Dirichlet distribution and an infinite mixture model with the Dirichlet Process In practice Dirichlet Process inference algorithm is approximated and uses a truncated distribution with a fixed maximum number of components called the Stickbreaking representation The number of components actually used almost always depends on the data

The next figure compares the results obtained for the different type of the weight concentration prior parameter `weightconcentrationpriortype` for different values of `weightconcentrationprior` Here we can see the value of the `weightconcentrationprior` parameter has a strong impact on the effective number of active components obtained We can also notice that large values for the concentration weight prior lead to more uniform weights when the type of prior is 'dirichletdistribution' while this is not necessarily the case for the 'dirichletprocess' type used by default

The examples below compare Gaussian mixture models with a fixed number of components to the variational Gaussian mixture models with a Dirichlet process prior. Here a classical Gaussian mixture is fitted with 5 components on a dataset composed of 2 clusters. We can see that the variational Gaussian mixture with a Dirichlet process prior is able to limit itself to only 2 components whereas the Gaussian mixture fits the data with a fixed number of components that has to be set a priori by the user. In this case the user has selected `ncomponents=5` which does not match the true generative distribution of this toy dataset. Note that with very little observations the variational Gaussian mixture models with a Dirichlet process prior can take a conservative stand and fit only one component. On the following figure we are fitting a dataset not well depicted by a Gaussian mixture. Adjusting the `weightconcentrationprior` parameter of the `BayesianGaussianMixture` controls the number of

ferentweightconcentrationpriortype for different values of the parameter

weightconcentrationprior

Pros and cons of variational inference with BayesianGaussianMixture

Pros

Automatic selection whenweightconcentrationprior is small enough and ncomponents is larger than what is found necessary by the model the Variational Bayesian mixture model has a natural tendency to set some mixture weights values close to zero This makes it possible to let the model choose a suitable number of effective components automatically Only an upper bound of this number needs to be provided Note however that the “ideal” number of active components is very application specific and is typically illdefined in a data exploration setting Less sensitivity to the number of parameters unlike finite models which will almost always use all components as much as they can and hence will produce wildly different solutions for different numbers of components the variational inference with a Dirichlet process prior weightconcentrationpriortypedirichletprocess won’t change much with changes to the parameters leading to more stability and less tuning Regularization due to the incorporation of prior information variational solutions have less pathological special cases than expectationmaximization solutions

Cons

Speed the extra parametrization necessary for variational inference make inference slower although not by much Hyperparameters this algorithm needs an extra hyperparameter that might need experimental tuning via crossvalidation Bias there are many implicit biases in the inference algorithms and also in the Dirichlet process if used and whenever there is a mismatch between these biases and the data it might be possible to fit better models using a finite mixture

The Dirichlet Process

Here we describe variational inference algorithms on Dirichlet process mixture The Dirichlet process is a prior probability distribution on clusterings with an infinite unbounded number of partitions Variational techniques let us incorporate this prior structure on Gaussian mixture models at almost no penalty in inference time comparing with a finite Gaussian mixture model

An important question is how can the Dirichlet process use an infinite unbounded number of clusters and still be consistent While a full explanation doesn’t fit this manual one can think of its stick breaking process analogy to help understanding it The stick breaking process is a generative story for the Dirichlet process We start with a unitlength stick and in each step we break off a portion of the remaining stick Each time we associate the length of the piece of the stick to the proportion of points that falls into a group of the mixture At the end to represent the infinite mixture we associate the last remaining piece of the stick to the proportion of points that don’t fall into all the other groups The length of each piece is a random variable with probability proportional to the concentration parameter Smaller value of the concentration will divide the unitlength into larger pieces of the stick defining more concentrated distribution Larger concentration values will create smaller pieces of the stick increasing the number of components with non zero weights

scikitlearn user guide Release 0213

Variational inference techniques for the Dirichlet process still work with a finite approximation to this infinite mixture model but instead of having to specify a priori how many components one wants to use one just specifies the concentration parameter and an upper bound on the number of mixture components this upper bound assuming it is higher than the “true” number of components affects only algorithmic complexity not the actual number of components used

322 Manifold learning

Look for the bare necessities

The simple bare necessities

Forget about your worries and your strife

I mean the bare necessities

Old Mother Nature’s recipes

That bring the bare necessities of life

– Baloo’s song The Jungle Book

Manifold learning is an approach to nonlinear dimensionality reduction Algorithms for this task are based on the idea that the dimensionality of many data sets is only artificially high

Introduction

Highdimensional datasets can be very difficult to visualize While data in two or three dimensions can be plotted to show the inherent structure of the data equivalent highdimensional plots are much less intuitive To aid visualization of the structure of a dataset the dimension must be reduced in some way

The simplest way to accomplish this dimensionality reduction is by taking a random projection of the data Though this allows some degree of visualization of the data structure the randomness of the choice leaves much to be desired In a random projection it is likely that the more interesting structure within the data will be lost

32 Unsupervised learning 343

To address this concern a number of supervised and unsupervised linear dimensionality reduction frameworks have been designed such as Principal Component Analysis PCA (Principal Component Analysis) Independent Component Analysis Linear Discriminant Analysis and others These algorithms define specific rubrics to choose an “interesting” linear projection of the data These methods can be powerful but often miss important nonlinear structure in the data Manifold Learning can be thought of as an attempt to generalize linear frameworks like PCA (Principal Component Analysis) to be sensitive to non linear structure in data Though supervised variants exist the typical manifold learning problem is unsupervised it learns the highdimensional structure of the data from the data itself without the use of predetermined classifications

Examples

- See Manifold learning on handwritten digits Locally Linear Embedding Isomap for an example of dimensionality reduction on handwritten digits
- See Comparison of Manifold Learning methods for an example of dimensionality reduction on a toy “S curve” dataset

The manifold learning implementations available in scikitlearn are summarized below

Isomap

One of the earliest approaches to manifold learning is the Isomap algorithm short for Isometric Mapping Isomap can be viewed as an extension of Multidimensional Scaling MDS or Kernel PCA (Principal Component Analysis) Isomap seeks a lowerdimensional

344 Chapter 3 User Guide

scikitlearn user guide Release 0213

embedding which maintains geodesic distances between all points Isomap can be performed with the object Isomap Complexity

The Isomap algorithm comprises three stages

1Nearest neighbor search Isomap uses sklearnneighborsBallTree for efficient neighbor search

The cost is approximately $\log \log$ for nearest neighbors of points in dimensions

2Shortestpath graph search The most efficient known algorithms for this are Dijkstra’s Algorithm which is approximately $2 \log$ or the FloydWarshall algorithm which is 3 The algorithm can be selected by the user with the pathmethod keyword of Isomap If unspecified the code attempts to choose the best algorithm for the input data

3Partial eigenvalue decomposition The embedding is encoded in the eigenvectors corresponding to the largest eigenvalues of the \times isomap kernel For a dense solver the cost is approximately 2 This cost can often be improved using the ARPACK solver The eigensolver can be specified by the user with the pathmethod keyword of Isomap If unspecified the code attempts to choose the best algorithm for the input data

The overall complexity of Isomap is $\log \log 2 \log 2$

- number of training data points
- input dimension
- number of nearest neighbors
- output dimension

Locally Linear Embedding

Locally linear embedding LLE seeks a lowerdimensional projection of the data which preserves distances within local neighborhoods It can be thought of as a series of local Principal Component Analyses which are globally compared to find the best nonlinear embedding

Locally linear embedding can be performed with function `locallylinearemb` or its objectoriented counterpart `LocallyLinearEmbedding`

Complexity

The standard LLE algorithm comprises three stages

1Nearest Neighbors Search See discussion under Isomap above

2Weight Matrix Construction $\mathcal{O}(n^3)$ The construction of the LLE weight matrix involves the solution of $a \times n$ linear equation for each of the n local neighborhoods

3Partial Eigenvalue Decomposition See discussion under Isomap above

The overall complexity of standard LLE is $\mathcal{O}(n \log n \log n)$ $\mathcal{O}(n^3)$ $\mathcal{O}(n^2)$

- n number of training data points
- n input dimension
- n number of nearest neighbors
- n output dimension

Modified Locally Linear Embedding

One wellknown issue with LLE is the regularization problem When the number of neighbors is greater than the number of input dimensions the matrix defining each local neighborhood is rankdeficient To address this standard 346 Chapter 3 User Guide

LLE applies an arbitrary regularization parameter λ which is chosen relative to the trace of the local weight matrix. Though it can be shown formally that as $\lambda \rightarrow 0$ the solution converges to the desired embedding there is no guarantee that the optimal solution will be found for $\lambda = 0$. This problem manifests itself in embeddings which distort the underlying geometry of the manifold.

One method to address the regularization problem is to use multiple weight vectors in each neighborhood.

This is the essence of modified locally linear embedding (MLLE). MLLE can be performed with function

`locallylinearembd` or its object-oriented counterpart `LocallyLinearEmbedding` with the key

`wordmethod` modified. It requires `nneighbors` `ncomponents`.

Complexity

The MLLE algorithm comprises three stages:

1. Nearest Neighbors Search: Same as standard LLE.

2. Weight Matrix Construction: Approximately $O(n^3 + k^2n)$. The first term is exactly equivalent to that of standard LLE. The second term has to do with constructing the weight matrix from multiple weights. In practice the added cost of constructing the MLLE weight matrix is relatively small compared to the cost of steps 1 and 3.

3. Partial Eigenvalue Decomposition: Same as standard LLE.

The overall complexity of MLLE is $O(n \log n + k^2 \log n + k^3 + k^2n)$.

- n : number of training data points
- k : input dimension
- k : number of nearest neighbors
- k : output dimension

Hessian Eigenmapping

Hessian Eigenmapping also known as Hessianbased LLE HLLLE is another method of solving the regularization problem of LLE It revolves around a hessianbased quadratic form at each neighborhood which is used to recover the locally linear structure Though other implementations note its poor scaling with data size sklearn implements some algorithmic improvements which make its cost comparable to that of other LLE variants for small output dimension HLLLE can be performed with function locallylinearembembedding or its objectoriented counterpart LocallyLinearEmbedding with the keyword method hessian It requires nneighbors

ncomponents ncomponents 3 2

Complexity

The HLLLE algorithm comprises three stages

1Nearest Neighbors Search Same as standard LLE

2Weight Matrix Construction Approximately $O(n^3 \log n)$ The first term reflects a similar cost to that of standard LLE The second term comes from a QR decomposition of the local hessian estimator

3Partial Eigenvalue Decomposition Same as standard LLE

The overall complexity of standard HLLLE is $O(n \log n \log n)$

- n number of training data points
- d input dimension
- k number of nearest neighbors
- d' output dimension

Spectral Embedding

Spectral Embedding is an approach to calculating a nonlinear embedding Scikitlearn implements Laplacian Eigen maps which finds a low dimensional representation of the data using a spectral decomposition of the graph Laplacian The graph generated can be considered as a discrete approximation of the low dimensional manifold in the high dimensional space Minimization of a cost function based on the graph ensures that points close to each other on the manifold are mapped close to each other in the low dimensional space preserving local distances Spectral embedding can be performed with the function `spectralembedding` or its objectoriented counterpart `SpectralEmbedding`

Complexity

The Spectral Embedding Laplacian Eigenmaps algorithm comprises three stages

1Weighted Graph Construction Transform the raw input data into graph representation using affinity adjacency matrix representation

2Graph Laplacian Construction unnormalized Graph Laplacian is constructed as $L = D - A$ for and normalized one as $L_{\text{norm}} = D^{-1/2} L D^{-1/2}$

2 D - A - 1

2

3Partial Eigenvalue Decomposition Eigenvalue decomposition is done on graph Laplacian

The overall complexity of spectral embedding is $O(n \log n \log n + n^3 + n^2)$

- n number of training data points
- n input dimension
- n number of nearest neighbors
- n output dimension

Local Tangent Space Alignment

Though not technically a variant of LLE Local tangent space alignment LTSA is algorithmically similar enough to LLE that it can be put in this category Rather than focusing on preserving neighborhood distances as in LLE LTSA seeks to characterize the local geometry at each neighborhood via its tangent space and performs a global optimization to align these local tangent spaces to learn the embedding LTSA can be performed with function `locallylinearembembedding` or its objectoriented counterpart `LocallyLinearEmbedding` with the key word `method Itsa`

Complexity

The LTSA algorithm comprises three stages

1Nearest Neighbors Search Same as standard LLE

2Weight Matrix Construction Approximately $O(n^3 + n^2)$ The first term reflects a similar cost to that of standard LLE

3Partial Eigenvalue Decomposition Same as standard LLE

32 Unsupervised learning 349

scikitlearn user guide Release 0213

The overall complexity of standard LTSA is $O(n \log n \log n)$ where n is the number of training data points

- n number of training data points
- d input dimension
- k number of nearest neighbors
- m output dimension

Multidimensional Scaling MDS

Multidimensional scaling MDS seeks a lowdimensional representation of the data in which the distances respect well the distances in the original highdimensional space

In general is a technique used for analyzing similarity or dissimilarity data MDS attempts to model similarity or dissimilarity data as distances in a geometric spaces The data can be ratings of similarity between objects interaction frequencies of molecules or trade indices between countries

There exists two types of MDS algorithm metric and non metric In the scikitlearn the class MDS implements both In Metric MDS the input similarity matrix arises from a metric and thus respects the triangular inequality the distances between output two points are then set to be as close as possible to the similarity or dissimilarity data In the nonmetric version the algorithms will try to preserve the order of the distances and hence seek for a monotonic relationship between the distances in the embedded space and the similaritiesdissimilarities

Let S be the similarity matrix and X the coordinates of the n input points Disparities Δ are transformation of the similarities chosen in some optimal ways The objective called the stress is then defined by $\sum_{i,j} (\Delta_{ij} - d_{ij})^2$

Metric MDS

The simplest metric MDS model called absolute MDS disparities are defined by $\Delta_{ij} = d_{ij}$ With absolute MDS the value Δ_{ij} should then correspond exactly to the distance between point i and j in the embedding point

scikitlearn user guide Release 0213

Most commonly disparities are set to $\frac{1}{2}(d_{ij}^2 - d_{ij}^*)^2$

Nonmetric MDS

Non metric MDS focuses on the ordination of the data If d_{ij} is the distance between x_i and x_j then the embedding should enforce $d_{ij} \leq d_{ij}^*$

A simple algorithm to enforce that is to use a monotonic regression of d_{ij}^* on d_{ij} yielding disparities d_{ij}^* in the same order as d_{ij}

A trivial solution to this problem is to set all the points on the origin In order to avoid that the disparities d_{ij}^* are normalized

tdistributed Stochastic Neighbor Embedding tSNE

tSNE TSNE converts affinities of data points to probabilities The affinities in the original space are represented by Gaussian joint probabilities and the affinities in the embedded space are represented by Student’s tdistributions This allows tSNE to be particularly sensitive to local structure and has a few other advantages over existing techniques

- Revealing the structure at many scales on a single map
- Revealing data that lie in multiple different manifolds or clusters
- Reducing the tendency to crowd points together at the center

While Isomap LLE and variants are best suited to unfold a single continuous low dimensional manifold tSNE will focus on the local structure of the data and will tend to extract clustered local groups of samples as highlighted on the Scurve example This ability to group samples based on the local structure might be beneficial to visually disentangle a dataset that comprises several manifolds at once as is the case in the digits dataset

The KullbackLeibler KL divergence of the joint probabilities in the original space and the embedded space will be minimized by gradient descent Note that the KL divergence is not convex ie multiple restarts with different initializations will end up in local minima of the KL divergence Hence it is sometimes useful to try different seeds and select the embedding with the lowest KL divergence

The disadvantages to using tSNE are roughly

- tSNE is computationally expensive and can take several hours on millionsample datasets where PCA (Principal Component Analysis) will finish in seconds or minutes
- The BarnesHut tSNE method is limited to two or three dimensional embeddings
- The algorithm is stochastic and multiple restarts with different seeds can yield different embeddings However it is perfectly legitimate to pick the embedding with the least error
- Global structure is not explicitly preserved This problem is mitigated by initializing points with PCA (Principal Component Analysis) using initpca

Optimizing tSNE

The main purpose of tSNE is visualization of highdimensional data Hence it works best when the data will be embedded on two or three dimensions

Optimizing the KL divergence can be a little bit tricky sometimes There are five parameters that control the optimization of tSNE and therefore possibly the quality of the resulting embedding

- perplexity
- early exaggeration factor
- learning rate
- maximum number of iterations
- angle not used in the exact method

The perplexity is defined as $2^{\frac{1}{\log_2 \frac{1}{\sum_{j=1}^k p_j}}}$ where $\frac{1}{\sum_{j=1}^k p_j}$ is the Shannon entropy of the conditional probability distribution The perplexity of a k -sided die is k so that $\frac{1}{\sum_{j=1}^k p_j}$ is effectively the number of nearest neighbors tSNE considers when generating the conditional probabilities Larger perplexities lead to more nearest neighbors and less sensitive to small structure Conversely a lower perplexity considers a smaller number of neighbors and thus ignores more global information in favour of the local neighborhood As dataset sizes get larger more points will be required to get a reasonable sample of the local neighborhood and hence larger perplexities may be required Similarly noisier datasets will require larger perplexity values to encompass enough local neighbors to see beyond the background noise The maximum number of iterations is usually high enough and does not need any tuning The optimization consists of two phases the early exaggeration phase and the final optimization During early exaggeration the joint probabilities in the original space will be artificially increased by multiplication with a given factor Larger factors result in larger gaps between natural clusters in the data If the factor is too high the KL divergence could increase during this phase Usually it does not have to be tuned A critical parameter is the learning rate If it is too low gradient descent will get stuck in a bad local minimum If it is too high the KL divergence will increase during optimization More tips can be found in Laurens van der Maaten’s FAQ see references The last parameter angle is a tradeoff between performance and accuracy Larger angles imply that we can approximate larger regions by a single point leading to better speed but less accurate results

“How to Use tSNE Effectively” provides a good discussion of the effects of the various parameters as well as interactive plots to explore the effects of different parameters

BarnesHut tSNE

The BarnesHut tSNE that has been implemented here is usually much slower than other manifold learning algorithms The optimization is quite difficult and the computation of the gradient is $O(n^2 \log n)$ where n is the number of output dimensions and n is the number of samples The BarnesHut method improves on the exact method where tSNE complexity is $O(n^3)$ but has several other notable differences

- The BarnesHut implementation only works when the target dimensionality is 3 or less The 2D case is typical when building visualizations
- BarnesHut only works with dense input data Sparse data matrices can only be embedded with the exact method or can be approximated by a dense low rank projection for instance using `sklearn.decomposition`

TruncatedSVD

- BarnesHut is an approximation of the exact method The approximation is parameterized with the angle parameter therefore the angle parameter is unused when method “exact”
- BarnesHut is significantly more scalable BarnesHut can be used to embed hundred of thousands of data points while the exact method can handle thousands of samples before becoming computationally intractable

scikitlearn user guide Release 0213

For visualization purpose which is the main use case of tSNE using the BarnesHut method is strongly recommended. The exact tSNE method is useful for checking the theoretically properties of the embedding possibly in higher dimensional space but limit to small datasets due to computational constraints. Also note that the digits labels roughly match the natural grouping found by tSNE while the linear 2D projection of the PCA (Principal Component Analysis) model yields a representation where label regions largely overlap. This is a strong clue that this data can be well separated by non linear methods that focus on the local structure eg an SVM (Support Vector Machine) with a Gaussian RBF (Radial Basis Function). However failing to visualize well separated homogeneously labeled groups with tSNE in 2D does not necessarily imply that the data cannot be correctly classified by a supervised model. It might be the case that 2 dimensions are not low enough to accurately represents the internal structure of the data.

Tips on practical use

- Make sure the same scale is used over all features. Because manifold learning methods are based on a nearest neighbor search the algorithm may perform poorly otherwise. See StandardScaler for convenient ways of scaling heterogeneous data.
- The reconstruction error computed by each routine can be used to choose the optimal output dimension. For a d -dimensional manifold embedded in a D -dimensional parameter space the reconstruction error will decrease as n components is increased until n components $\approx d$.
- Note that noisy data can “shortcircuit” the manifold in essence acting as a bridge between parts of the manifold that would otherwise be well separated. Manifold learning on noisy and/or incomplete data is an active area of research.
- Certain input configurations can lead to singular weight matrices for example when more than two points in the dataset are identical or when the data is split into disjointed groups. In this case solver arpack will fail to find the null space. The easiest way to address this is to use solver dense which will work on a singular matrix though it may be very slow depending on the number of input points. Alternatively one can attempt to understand the source of the singularity if it is due to disjoint sets increasing `n_neighbors` may help. If it is due to identical points in the dataset removing these points may help.

See also

Totally Random Trees Embedding can also be useful to derive nonlinear representations of feature space also it does not perform dimensionality reduction.

323 Clustering

Clustering of unlabeled data can be performed with the module `sklearn.cluster`.

Each clustering algorithm comes in two variants: a class that implements the `fit` method to learn the clusters on train data and a function that given train data returns an array of integer labels corresponding to the different clusters. For the class the labels over the training data can be found in the `labels` attribute.

354 Chapter 3 User Guide

Input data

One important thing to note is that the algorithms implemented in this module can take different kinds of matrix as input. All the methods accept standard data matrices of shape `nsamples nfeatures`. These can be obtained from the classes in the `sklearnfeatureextraction` module. For `AffinityPropagation`, `SpectralClustering` and `DBSCAN` one can also input similarity matrices of shape `nsamples nsamples`. These can be obtained from the functions in the `sklearnmetricspairwise` module.

Overview of clustering methods

Fig 34 A comparison of the clustering algorithms in scikitlearn

scikitlearn user guide Release 0.21.3

points from μ although they live in the same space

The Kmeans algorithm aims to choose centroids that minimise the inertia or within cluster sum of squares criterion

$$\sum$$

$$\mu \in \mathbb{R}^d$$

$$\mu \in \mathbb{R}^d - \mathbb{R}^d$$

Inertia can be recognized as a measure of how internally coherent clusters are. It suffers from various drawbacks

- Inertia makes the assumption that clusters are convex and isotropic which is not always the case. It responds poorly to elongated clusters or manifolds with irregular shapes.
- Inertia is not a normalized metric; we just know that lower values are better and zero is optimal. But in very high-dimensional spaces, Euclidean distances tend to become inflated; this is an instance of the so-called “curse of dimensionality”. Running a dimensionality reduction algorithm such as Principal Component Analysis (PCA) prior to kmeans clustering can alleviate this problem and speed up the computations.

K-means is often referred to as Lloyd’s algorithm. In basic terms, the algorithm has three steps. The first step chooses the initial centroids with the most basic method being to choose k samples from the dataset. After initialization, 32 Unsupervised learning 357

scikitlearn user guide Release 0213

Kmeans consists of looping between the two other steps The first step assigns each sample to its nearest centroid The second step creates new centroids by taking the mean value of all of the samples assigned to each previous centroid The difference between the old and the new centroids are computed and the algorithm repeats these last two steps until this value is less than a threshold In other words it repeats until the centroids do not move significantly Kmeans is equivalent to the expectationmaximization algorithm with a small allequal diagonal covariance matrix

The algorithm can also be understood through the concept of V oronoi diagrams First the V oronoi diagram of the points is calculated using the current centroids Each segment in the V oronoi diagram becomes a separate cluster Secondly the centroids are updated to the mean of each segment The algorithm then repeats this until a stopping criterion is fulfilled Usually the algorithm stops when the relative decrease in the objective function between iterations is less than the given tolerance value This is not the case in this implementation iteration stops when centroids move less than the tolerance

Given enough time Kmeans will always converge however this may be to a local minimum This is highly depen dent on the initialization of the centroids As a result the computation is often done several times with different initializations of the centroids One method to help address this issue is the kmeans initialization scheme which has been implemented in scikitlearn use the initkmeans parameter This initializes the centroids to be generally distant from each other leading to provably better results than random initialization as shown in the reference

The algorithm supports sample weights which can be given by a parameter sampleweight This allows to assign more weight to some samples when computing cluster centers and values of inertia For example assigning a weight of 2 to a sample is equivalent to adding a duplicate of that sample to the dataset

A parameter can be given to allow Kmeans to be run in parallel called njobs Giving this parameter a positive value uses that many processors default 1 A value of 1 uses all available processors with 2 using one less and so on Parallelization generally speeds up computation at the cost of memory in this case multiple copies of centroids need to be stored one for each job

Warning The parallel version of KMeans is broken on OS X when numpy uses theAccelerate Framework

This is expected behavior Accelerate can be called after a fork but you need to execv the subprocess with the Python binary which multiprocessing does not do under posix

Kmeans can be used for vector quantization This is achieved using the transform method of a trained model of KMeans

Examples

Mini Batch KMeans

TheMiniBatchKMeans is a variant of the KMeans algorithm which uses minibatches to reduce the computation time while still attempting to optimise the same objective function Minibatches are subsets of the input data randomly sampled in each training iteration These minibatches drastically reduce the amount of computation required to converge to a local solution In contrast to other algorithms that reduce the convergence time of kmeans minibatch kmeans produces results that are generally only slightly worse than the standard algorithm

The algorithm iterates between two major steps similar to vanilla kmeans In the first step n samples are drawn randomly from the dataset to form a minibatch These are then assigned to the nearest centroid In the second step the centroids are updated In contrast to kmeans this is done on a per sample basis For each sample in the minibatch the assigned centroid is updated by taking the streaming average of the sample and all previous samples assigned to that centroid This has the effect of decreasing the rate of change for a centroid over time These steps are performed until convergence or a predetermined number of iterations is reached

MiniBatchKMeans converges faster than KMeans but the quality of the results is reduced In practice this difference in quality can be quite small as shown in the example and cited reference

Examples

- Comparison of the KMeans and MiniBatchKMeans clustering algorithms Comparison of KMeans and MiniBatchKMeans
- Clustering text documents using kmeans Document clustering using sparse MiniBatchKMeans
- Online learning of a dictionary of parts of faces

Affinity Propagation

AffinityPropagation creates clusters by sending messages between pairs of samples until convergence A dataset is then described using a small number of exemplars which are identified as those most representative of other samples The messages sent between pairs represent the suitability for one sample to be the exemplar of the other which is updated in response to the values from other pairs This updating happens iteratively until convergence at which point the final exemplars are chosen and hence the final clustering is given Affinity Propagation can be interesting as it chooses the number of clusters based on the data provided For this purpose the two important parameters are the preference which controls how many exemplars are used and the damping factor which damps the responsibility and availability messages to avoid numerical oscillations when updating these messages

The main drawback of Affinity Propagation is its complexity The algorithm has a time complexity of the order $O(n^2 \cdot i)$ where n is the number of samples and i is the number of iterations until convergence Further the memory complexity is of the order $O(n^2)$ if a dense similarity matrix is used but reducible if a sparse similarity matrix is used This makes Affinity Propagation most appropriate for small to medium sized datasets

Examples

- Demo of affinity propagation clustering algorithm Affinity Propagation on a synthetic 2D datasets with 3 classes
- Visualizing the stock market structure Affinity Propagation on Financial time series to find groups of companies

Algorithm description The messages sent between points belong to one of two categories The first is the responsibility r_{ij} which is the accumulated evidence that sample j should be the exemplar for sample i The second is the availability a_{ij} which is the accumulated evidence that sample i should choose sample j to be its exemplar and considers the values for all other samples that j should be an exemplar In this way exemplars are chosen by samples if they are 1 similar enough to many samples and 2 chosen by many samples to be representative of themselves

More formally the responsibility of a sample i to be the exemplar of sample j is given by

$$r_{ji} \leftarrow \frac{1 - \max_{k \neq i} s_{jk}}{\sum_{k=1}^K (1 - \max_{k \neq i} s_{jk})}$$

Where s_{ji} is the similarity between samples i and j . The availability of sample i to be the exemplar of sample j is given by

$$a_{ji} \leftarrow \frac{1}{\sum_{k=1}^K r_{jk}}$$

$$r'_{ji} \in [0, 1]$$

To begin with all values for r and a are set to zero and the calculation of each iterates until convergence As discussed above in order to avoid numerical oscillations when updating the messages the damping factor α is introduced to iteration process

$$r'_{ji} \leftarrow \alpha \cdot r_{ji} + (1 - \alpha) \cdot a_{ji}$$

$$a'_{ji} \leftarrow \alpha \cdot a_{ji} + (1 - \alpha) \cdot r_{ji}$$

where t indicates the iteration times

Mean Shift

MeanShift clustering aims to discover blobs in a smooth density of samples It is a centroid based algorithm which works by updating candidates for centroids to be the mean of the points within a given region These candidates are then filtered in a postprocessing stage to eliminate nearduplicates to form the final set of centroids

Given a candidate centroid μ for iteration t the candidate is updated according to the following equation

$$\mu^{t+1}$$

$$= \frac{1}{n} \sum_{x \in N(\mu)}$$

$$\mu$$

Where $N(\mu)$ is the neighborhood of samples within a given distance around μ and μ is the mean shift vector that is computed for each centroid that points towards a region of the maximum increase in the density of points This is computed using the following equation effectively updating a centroid to be the mean of the samples within its neighborhood

$$\mu^{t+1} = \mu^t + \frac{1}{n} \sum_{x \in N(\mu^t)} (x - \mu^t)$$

$$\mu^t \in \mathbb{R}^d$$

$$\mu^t \in \mathbb{R}^d$$

The algorithm automatically sets the number of clusters instead of relying on a parameter bandwidth which dictates the size of the region to search through This parameter can be set manually but can be estimated using the provided estimatebandwidth function which is called if the bandwidth is not set

The algorithm is not highly scalable as it requires multiple nearest neighbor searches during the execution of the algorithm The algorithm is guaranteed to converge however the algorithm will stop iterating when the change in centroids is small

Labelling a new sample is performed by finding the nearest centroid for a given sample

Examples

Spectral clustering

SpectralClustering does a lowdimension embedding of the affinity matrix between samples followed by a KMeans in the low dimensional space It is especially efficient if the affinity matrix is sparse and the pyamg module is installed SpectralClustering requires the number of clusters to be specified It works well for a small number of clusters but is not advised when using many clusters

For two clusters it solves a convex relaxation of the normalised cuts problem on the similarity graph cutting the graph in two so that the weight of the edges cut is small compared to the weights of the edges inside each cluster This criteria is especially interesting when working on images graph vertices are pixels and edges of the similarity graph are a function of the gradient of the image

Warning Transforming distance to wellbehaved similarities

Note that if the values of your similarity matrix are not well distributed eg with negative values or with a distance

scikitlearn user guide Release 0213

matrix rather than a similarity the spectral problem will be singular and the problem not solvable In which case it is advised to apply a transformation to the entries of the matrix For instance in the case of a signed distance matrix is common to apply a heat kernel
similarity npexpbeta distance distancestd
See the examples for such an application

Examples

- Spectral clustering for image segmentation Segmenting objects from a noisy background using spectral clustering

- Segmenting the picture of greek coins in regions Spectral clustering to split the image of coins in regions

Different label assignment strategies

Different label assignment strategies can be used corresponding to the assignlabels parameter of SpectralClustering Thekmeans strategy can match finer details of the data but it can be more unstable In particular unless you control the randomstate it may not be reproducible from runtorun as it depends on a random initialization On the other hand the discretize strategy is 100 reproducible but it tends to create parcels of fairly even and geometrical shape
assignlabelskmeans assignlabelsdiscretize

Spectral Clustering Graphs

Spectral Clustering can also be used to cluster graphs by their spectral embeddings In this case the affinity matrix is the adjacency matrix of the graph and SpectralClustering is initialized with affinityprecomputed

32 Unsupervised learning 363

```
scikitlearn user guide Release 0213
from sklearncluster import SpectralClustering
sc SpectralClustering3 affinityprecomputed ninit100
assignlabelsdiscretize

Hierarchical clustering

Hierarchical clustering is a general family of clustering algorithms that build nested clusters by merging or splitting them successively This hierarchy of clusters is represented as a tree or dendrogram The root of the tree is the unique cluster that gathers all the samples the leaves being the clusters with only one sample See the Wikipedia page for more details

TheAgglomerativeClustering object performs a hierarchical clustering using a bottom up approach each observation starts in its own cluster and clusters are successively merged together The linkage criteria determines the metric used for the merge strategy

- Ward minimizes the sum of squared differences within all clusters It is a varianceminimizing approach and in this sense is similar to the kmeans objective function but tackled with an agglomerative hierarchical approach
- Maximum orcomplete linkage minimizes the maximum distance between observations of pairs of clusters
- Average linkage minimizes the average of the distances between all observations of pairs of clusters
- Single linkage minimizes the distance between the closest observations of pairs of clusters

AgglomerativeClustering can also scale to large number of samples when it is used jointly with a connectivity matrix but is computationally expensive when no connectivity constraints are added between samples it considers at each step all the possible merges

FeatureAgglomeration

TheFeatureAgglomeration uses agglomerative clustering to group together features that look very similar thus decreasing the number of features It is a dimensionality reduction tool see Unsupervised dimensionality reduction

Different linkage type Ward complete average and single linkage

AgglomerativeClustering supports Ward single average and complete linkage strategies

Ag

glomerative cluster has a “rich get richer” behavior that leads to uneven cluster sizes In this regard single linkage is the worst strategy and Ward gives the most regular sizes However the affinity or distance used in clustering cannot be varied with Ward thus for non Euclidean metrics average linkage is a good alternative Single linkage while not robust to noisy data can be computed very efficiently and can therefore be useful to provide hierarchical clustering of larger datasets Single linkage can also perform well on nonglobular data

Examples

- Various Agglomerative Clustering on a 2D embedding of digits exploration of the different linkage strategies in a real dataset

Adding connectivity constraints

An interesting aspect of AgglomerativeClustering is that connectivity constraints can be added to this algorithm only adjacent clusters can be merged together through a connectivity matrix that defines for each sample the neighboring samples following a given structure of the data For instance in the swissroll example below the connectivity constraints forbid the merging of points that are not adjacent on the swiss roll and thus avoid forming clusters that extend across overlapping folds of the roll
These constraint are useful to impose a certain local structure but they also make the algorithm faster especially when the number of the samples is high

The connectivity constraints are imposed via an connectivity matrix a scipy sparse matrix that has elements only at the intersection of a row and a column with indices of the dataset that should be connected This matrix can be constructed from apriori information for instance you may wish to cluster web pages by only merging pages with a link pointing from one to another It can also be learned from the data for instance using sklearn.neighbors.kneighborsgraph to restrict merging to nearest neighbors as in this example or using sklearn.feature_extraction.image.grid_to_graph to enable only merging of neighboring pixels on an image as in the coin example

Examples

- A demo of structured Ward hierarchical clustering on an image of coins Ward clustering to split the image of coins in regions
- Hierarchical clustering structured vs unstructured ward Example of Ward algorithm on a swissroll comparison of structured approaches versus unstructured approaches
- Feature agglomeration vs univariate selection Example of dimensionality reduction with feature agglomeration based on Ward hierarchical clustering
- Agglomerative clustering with and without structure

Warning Connectivity constraints with single average and complete linkage
Connectivity constraints and single complete or average linkage can enhance the ‘rich getting richer’ aspect of agglomerative clustering particularly so if they are built with sklearn.neighbors.kneighborsgraph
In the limit of a small number of clusters they tend to give a few macroscopically occupied clusters and almost empty ones see the discussion in Agglomerative clustering with and without structure Single linkage is the most brittle linkage option with regard to this issue

Varying the metric

Single average and complete linkage can be used with a variety of distances or affinities in particular Euclidean distance l2 Manhattan distance or Cityblock or l1 cosine distance or any precomputed affinity matrix

- l1distance is often good for sparse features or sparse noise ie many of the features are zero as in text mining using occurrences of rare words

- cosine distance is interesting because it is invariant to global scalings of the signal

The guidelines for choosing a metric is to use one that maximizes the distance between samples in different classes and minimizes that within each class

Examples

- Agglomerative clustering with different metrics

DBSCAN

TheDBSCAN algorithm views clusters as areas of high density separated by areas of low density Due to this rather generic view clusters found by DBSCAN can be any shape as opposed to kmeans which assumes that clusters are convex shaped The central component to the DBSCAN is the concept of core samples which are samples that are in areas of high density A cluster is therefore a set of core samples each close to each other measured by some distance measure and a set of noncore samples that are close to a core sample but are not themselves core samples There are two parameters to the algorithm minsamples andeps which define formally what we mean when we say dense Higherminsamples or lowereps indicate higher density necessary to form a cluster

More formally we define a core sample as being a sample in the dataset such that there exist minsamples other samples within a distance of eps which are defined as neighbors of the core sample This tells us that the core sample is in a dense area of the vector space A cluster is a set of core samples that can be built by recursively taking a core sample finding all of its neighbors that are core samples finding all of their neighbors that are core samples and so on A cluster also has a set of noncore samples which are samples that are neighbors of a core sample in the cluster but are not themselves core samples Intuitively these samples are on the fringes of a cluster

scikitlearn user guide Release 0213

Any core sample is part of a cluster by definition Any sample that is not a core sample and is at least eps in distance from any core sample is considered an outlier by the algorithm

While the parameter minsamples primarily controls how tolerant the algorithm is towards noise on noisy and large data sets it may be desiable to increase this parameter the parameter eps iscrucial to choose appropriately for the data set and distance function and usually cannot be left at the default value It controls the local neighborhood of the points When chosen too small most data will not be clustered at all and labeled as 1for “noise” When chosen too large it causes close clusters to be merged into one cluster and eventually the entire data set to be returned as a single cluster Some heuristics for choosing this parameter have been discussed in literature for example based on a knee in the nearest neighbor distances plot as discussed in the references below

In the figure below the color indicates cluster membership with large circles indicating core samples found by the algorithm Smaller circles are noncore samples that are still part of a cluster Moreover the outliers are indicated by black points below

Examples

- Demo of DBSCAN clustering algorithm

Implementation

The DBSCAN algorithm is deterministic always generating the same clusters when given the same data in the same order However the results can differ when data is provided in a different order First even though the core samples will always be assigned to the same clusters the labels of those clusters will depend on the order in which those samples are encountered in the data Second and more importantly the clusters to which noncore samples are assigned can differ depending on the data order This would happen when a noncore sample has a distance lower thaneps to two core samples in different clusters By the triangular inequality those two core samples must be more distant than eps from each other or they would be in the same cluster The noncore sample is assigned to whichever cluster is generated first in a pass through the data and so the results will depend on the data ordering The current implementation uses ball trees and kdtrees to determine the neighborhood of points which avoids calculating the full distance matrix as was done in scikitlearn versions before 014 The possibility to use custom metrics is retained for details see NearestNeighbors

Memory consumption for large sample sizes

368 Chapter 3 User Guide

scikitlearn user guide Release 0213

This implementation is by default not memory efficient because it constructs a full pairwise similarity matrix in the case where kdtrees or balltrees cannot be used eg with sparse matrices This matrix will consume n^2 floats

A couple of mechanisms for getting around this are

- Use OPTICS clustering in conjunction with the extractdbscan method OPTICS clustering also calculates the full pairwise matrix but only keeps one row in memory at a time memory complexity n
- A sparse radius neighborhood graph where missing entries are presumed to be out of eps can be precomputed in a memoryefficient way and dbscan can be run over this with metricprecomputed See `sklearn.neighbors.NearestNeighbors.radius_neighbors_graph`
- The dataset can be compressed either by removing exact duplicates if these occur in your data or by using BIRCH Then you only have a relatively small number of representatives for a large number of points You can then provide a sampleweight when fitting DBSCAN

OPTICS

TheOPTICS algorithm shares many similarities with the DBSCAN algorithm and can be considered a generalization of DBSCAN that relaxes the eps requirement from a single value to a value range The key difference between DBSCAN and OPTICS is that the OPTICS algorithm builds a reachability graph which assigns each sample both areachability distance and a spot within the cluster ordering attribute these two attributes are assigned when the model is fitted and are used to determine cluster membership If OPTICS is run with the default value of `inf` for `maxeps` then DBSCAN style cluster extraction can be performed repeatedly in linear time for any given eps value using the `cluster_optics_dbscan` method Setting `maxeps` to a lower value will result in shorter run times and can be thought of as the maximum neighborhood radius from each point to find other potential reachable points

Thereachability distances generated by OPTICS allow for variable density extraction of clusters within a single data set As shown in the above plot combining reachability distances and data set ordering produces a reachability plot where point density is represented on the Yaxis and points are ordered such that nearby points are adjacent 'Cutting' the reachability plot at a single value produces DBSCAN like results all points above the 'cut' are classified as noise and each time that there is a break when reading from left to right signifies a new cluster The default cluster extraction with OPTICS looks at the steep slopes within the graph to find clusters and the user can define what counts as a steep slope using the parameter ξ There are also other possibilities for analysis on the graph itself such as generating hierarchical representations of the data through reachabilityplot dendrograms and the hierarchy of clusters detected by the algorithm can be accessed through the clusterhierarchy parameter The plot above has been colorcoded so that cluster colors in planar space match the linear segment clusters of the reachability plot Note that the blue and red clusters are adjacent in the reachability plot and can be hierarchically represented as children of a larger parent cluster

Examples

- Demo of OPTICS clustering algorithm

Comparison with DBSCAN

The results from OPTICS clusteropticsdbscan method and DBSCAN are very similar but not always identical specifically labeling of periphery and noise points This is in part because the first samples of each dense area processed by OPTICS have a large reachability value while being close to other points in their area and will thus sometimes be marked as noise rather than periphery This affects adjacent points when they are considered as candidates for being marked as either periphery or noise

Note that for any single value of ϵ DBSCAN will tend to have a shorter run time than OPTICS however for repeated runs at varying ϵ values a single run of OPTICS may require less cumulative runtime than DBSCAN It is also important to note that OPTICS' output is close to DBSCAN's only if ϵ and $\max\epsilon$ are close

scikitlearn user guide Release 0213

Computational Complexity

Spatial indexing trees are used to avoid calculating the full distance matrix and allow for efficient memory usage on large sets of samples Different distance metrics can be supplied via the metric keyword

For large datasets similar but not identical results can be obtained via HDBSCAN The HDBSCAN implementation is multithreaded and has better algorithmic runtime complexity than OPTICS at the cost of worse memory scaling For extremely large datasets that exhaust system memory using HDBSCAN OPTICS will maintain a solution in a reasonable amount of wall time

Birch

The Birch builds a tree called the Characteristic Feature Tree CFT for the given data The data is essentially lossy compressed to a set of Characteristic Feature nodes CF Nodes The CF Nodes have a number of subclusters called Characteristic Feature subclusters CF Subclusters and these CF Subclusters located in the nonterminal CF Nodes can have CF Nodes as children

The CF Subclusters hold the necessary information for clustering which prevents the need to hold the entire input data in memory This information includes

- Number of samples in a subcluster
- Linear Sum A ndimensional vector holding the sum of all samples
- Squared Sum Sum of the squared L2 norm of all samples
- Centroids To avoid recalculation linear sum / nsamples
- Squared norm of the centroids

The Birch algorithm has two parameters the threshold and the branching factor The branching factor limits the number of subclusters in a node and the threshold limits the distance between the entering sample and the existing subclusters

This algorithm can be viewed as an instance or data reduction method since it reduces the input data to a set of subclusters which are obtained directly from the leaves of the CFT This reduced data can be further processed by feeding it into a global clusterer This global clusterer can be set by nclusters If nclusters is set to None the subclusters from the leaves are directly read off otherwise a global clustering step labels these subclusters into global clusters labels and the samples are mapped to the global label of the nearest subcluster

Algorithm description

- A new sample is inserted into the root of the CF Tree which is a CF Node It is then merged with the subcluster of the root that has the smallest radius after merging constrained by the threshold and branching factor conditions If the subcluster has any child node then this is done repeatedly till it reaches a leaf After finding the nearest subcluster in the leaf the properties of this subcluster and the parent subclusters are recursively updated
- If the radius of the subcluster obtained by merging the new sample and the nearest subcluster is greater than the square of the threshold and if the number of subclusters is greater than the branching factor then a space is temporarily allocated to this new sample The two farthest subclusters are taken and the subclusters are divided into two groups on the basis of the distance between these subclusters

scikitlearn user guide Release 0213

- If this split node has a parent subcluster and there is room for a new subcluster then the parent is split into two
- If there is no room then this node is again split into two and the process is continued recursively till it reaches the root

Birch or MiniBatchKMeans

- Birch does not scale very well to high dimensional data As a rule of thumb if nfeatures is greater than twenty it is generally better to use MiniBatchKMeans
- If the number of instances of data needs to be reduced or if one wants a large number of subclusters either as a preprocessing step or otherwise Birch is more useful than MiniBatchKMeans

How to use partialfit

To avoid the computation of global clustering for every call of partialfit the user is advised

- 1 To setnclustersNone initially
- 2 Train all data by multiple calls to partialfit
- 3 Setnclusters to a required value using brcsetparamsnclustersnclusters
- 4 Callpartialfit finally with no arguments ie brcpartialfit which performs the global clustering

Clustering performance evaluation

Evaluating the performance of a clustering algorithm is not as trivial as counting the number of errors or the precision and recall of a supervised classification algorithm In particular any evaluation metric should not take the absolute values of the cluster labels into account but rather if this clustering define separations of the data similar to some ground truth set of classes or satisfying some assumption such that members belong to the same class are more similar that members of different classes according to some similarity metric

scikitlearn user guide Release 0213

Adjusted Rand index

Given the knowledge of the ground truth class assignments `labelstrue` and our clustering algorithm assignments of the same samples `labelspred` the adjusted Rand index is a function that measures the similarity of the two assignments ignoring permutations and with chance normalization

`from sklearn import metrics`

`labelstrue 0 0 0 1 1 1`

`labelspred 0 0 1 1 2 2`

`metricsadjustedrandscorelabelstrue labelspred`
024

One can permute 0 and 1 in the predicted labels rename 2 to 3 and get the same score

`labelspred 1 1 0 0 3 3`

`metricsadjustedrandscorelabelstrue labelspred`
024

Furthermore `adjustedrandscore` issymmetric swapping the argument does not change the score It can thus be used as a consensus measure

`metricsadjustedrandscorelabelspred labelstrue`
024

Perfect labeling is scored 10

`labelspred labelstrue`

`metricsadjustedrandscorelabelstrue labelspred`
10

Bad eg independent labelings have negative or close to 00 scores

`labelstrue 0 1 2 0 3 4 5 1`

`labelspred 1 1 0 0 2 2 2 2`

`metricsadjustedrandscorelabelstrue labelspred`
012

Advantages

- Random uniform label assignments have a ARI score close to 00 for any value of `nclusters` and `nsamples` which is not the case for raw Rand index or the Vmeasure for instance
- Bounded range 1 1 negative values are bad independent labelings similar clusterings have a positive ARI 10 is the perfect match score
- No assumption is made on the cluster structure can be used to compare clustering algorithms such as k means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes

Drawbacks

- Contrary to inertia ARI requires knowledge of the ground truth classes while is almost never available in practice or requires manual assignment by human annotators as in the supervised learning setting
- 32 Unsupervised learning 373

scikitlearn user guide Release 0213

However ARI can also be useful in a purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection TODO

Examples

- Adjustment for chance in clustering performance evaluation Analysis of the impact of the dataset size on the value of clustering measures for random assignments

Mathematical formulation

If C is a ground truth class assignment and K the clustering let us define n_{ii} and n_{ij} as

- n_{ii} the number of pairs of elements that are in the same set in C and in the same set in K
- n_{ij} the number of pairs of elements that are in different sets in C and in different sets in K

The raw unadjusted Rand index is then given by

$$RI = \frac{n_{ii} + \frac{1}{2} \sum_{i \neq j} n_{ij}}{\frac{N(N-1)}{2}}$$

Where $\frac{N(N-1)}{2}$

2 is the total number of possible pairs in the dataset without ordering

However the RI score does not guarantee that random label assignments will get a value close to zero esp if the number of clusters is in the same order of magnitude as the number of samples

To counter this effect we can discount the expected RI of random labelings by defining the adjusted Rand index as follows

$$ARI = \frac{RI - E[RI]}{\max RI - E[RI]}$$

Perfect labeling is scored 10

labelspred labelstrue

metricsadjustedmutualinfoscorelabelstrue labelspred
10

metricsnormalizedmutualinfoscorelabelstrue labelspred
10

This is not true for mutualinfoscore which is therefore harder to judge

metricsmutualinfoscorelabelstrue labelspred
069

Bad eg independent labelings have nonpositive scores

labelstrue 0 1 2 0 3 4 5 1

labelspred 1 1 0 0 2 2 2 2

metricsadjustedmutualinfoscorelabelstrue labelspred
010526

Advantages

- Random uniform label assignments have a AMI score close to 00 for any value of nclusters and nsamples which is not the case for raw Mutual Information or the Vmeasure for instance
- Upper bound of 1 Values close to zero indicate two label assignments that are largely independent while values close to one indicate significant agreement Further an AMI of exactly 1 indicates that the two label assignments are equal with or without permutation

Drawbacks

- Contrary to inertia MIbased measures require the knowledge of the ground truth classes while almost never available in practice or requires manual assignment by human annotators as in the supervised learning setting

However MIbased measures can also be useful in purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection

- NMI and MI are not adjusted against chance

Examples

32 Unsupervised learning 375

•Adjustment for chance in clustering performance evaluation Analysis of the impact of the dataset size on the value of clustering measures for random assignments This example also includes the Adjusted Rand Index

Mathematical formulation

Assume two label assignments of the same N objects \mathcal{X} and \mathcal{Y} Their entropy is the amount of uncertainty for a partition set defined by

$$H(\mathcal{X}) = -\sum_{i=1}^K p_i \log p_i$$

where p_i is the probability that an object picked at random from \mathcal{X} falls into class i Likewise for \mathcal{Y}

With p_{ij} The mutual information MI between \mathcal{X} and \mathcal{Y} is calculated by

$$MI(\mathcal{X}, \mathcal{Y}) = \sum_{i=1}^K \sum_{j=1}^L p_{ij} \log \frac{p_{ij}}{p_i p_j}$$

where p_{ij} is the probability that an object picked at random falls into both classes i and j It also can be expressed in set cardinality formulation

$$MI(\mathcal{X}, \mathcal{Y}) = \sum_{i=1}^K \sum_{j=1}^L \frac{|S_{ij}|}{N} \log \frac{|S_{ij}|}{|S_i| |S_j|}$$

The normalized mutual information is defined as

$$NMI(\mathcal{X}, \mathcal{Y}) = \frac{MI(\mathcal{X}, \mathcal{Y})}{\frac{H(\mathcal{X}) + H(\mathcal{Y})}{2}}$$

mean \mathcal{X}, \mathcal{Y}

This value of the mutual information and also the normalized variant is not adjusted for chance and will tend to increase as the number of different labels clusters increases regardless of the actual amount of “mutual information” between the label assignments

The expected value for the mutual information can be calculated using the following equation VEB2009 In this equation n_X the number of elements in \mathcal{X} and n_Y the number of elements in \mathcal{Y}

$$E[MI(\mathcal{X}, \mathcal{Y})] = \sum_{i=1}^K \sum_{j=1}^L \frac{1}{n_X n_Y} \log \frac{n_X n_Y}{n_X n_Y} = 0$$
$$E[NMI(\mathcal{X}, \mathcal{Y})] = \frac{E[MI(\mathcal{X}, \mathcal{Y})]}{\frac{H(\mathcal{X}) + H(\mathcal{Y})}{2}} = 0$$

Using the expected value the adjusted mutual information can then be calculated using a similar form to that of the adjusted Rand index

$$AMI = \frac{MI - E[MI]}{\max(MI, 1 - E[MI])}$$

For normalized mutual information and adjusted mutual information the normalizing value is typically some generalized mean of the entropies of each clustering Various generalized means exist and no firm rules exist for preferring one over the others The decision is largely a fieldbyfield basis for instance in community detection the arithmetic mean is most common Each normalizing method provides “qualitatively similar behaviours” YAT2016 In our implementation this is controlled by the averagemethod parameter

Vinh et al 2010 named variants of NMI and AMI by their averaging method VEB2010 Their ‘sqrt’ and ‘sum’ averages are the geometric and arithmetic means we use these more broadly common names

Homogeneity completeness and Vmeasure

Given the knowledge of the ground truth class assignments of the samples it is possible to define some intuitive metric using conditional entropy analysis

In particular Rosenberg and Hirschberg 2007 define the following two desirable objectives for any cluster assignment

- homogeneity each cluster contains only members of a single class
- completeness all members of a given class are assigned to the same cluster

We can turn those concept as scores homogeneityscore andcompletenessscore Both are bounded below by 00 and above by 10 higher is better

from sklearn import metrics

labelstrue 0 0 0 1 1 1

labelspred 0 0 1 1 2 2

metricshomogeneityscorelabelstrue labelspred

066

metricscompletenessscorelabelstrue labelspred

042

Their harmonic mean called Vmeasure is computed by vmeasurescore

metricsvmeasurescorelabelstrue labelspred

051

This function’s formula is as follows

$$V = \frac{1}{\beta + 1} (\beta \times \text{homogeneity} + \text{completeness})$$

↪
$$\beta \times \text{homogeneity} + \text{completeness}$$

beta defaults to a value of 10 but for using a value less than 1 for beta

metricsvmeasurescorelabelstrue labelspred beta06

054

more weight will be attributed to homogeneity and using a value greater than 1

metricsvmeasurescorelabelstrue labelspred beta18

048

more weight will be attributed to completeness

32 Unsupervised learning 377

scikitlearn user guide Release 0213

The Vmeasure is actually equivalent to the mutual information NMI discussed above with the aggregation function being the arithmetic mean B2011

Homogeneity completeness and Vmeasure can be computed at once using

homogeneitycompletenessvmeasure as follows

metricshomogeneitycompletenessvmeasurelabelstrue labelspred

066 042 051

The following clustering assignment is slightly better since it is homogeneous but not complete

labelspred 0 0 0 1 2 2

metricshomogeneitycompletenessvmeasurelabelstrue labelspred

10 068 081

Notevmeasurescore issymmetric it can be used to evaluate the agreement of two independent assignments on the same dataset

This is not the case for completenessscore andhomogeneityscore both are bound by the relationship

homogeneityscorea b completenessscoreb a

Advantages

- Bounded scores 00 is as bad as it can be 10 is a perfect score
- Intuitive interpretation clustering with bad Vmeasure can be qualitatively analyzed in terms of homogeneity and completeness to better feel what ‘kind’ of mistakes is done by the assignment
- No assumption is made on the cluster structure can be used to compare clustering algorithms such as k means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes

Drawbacks

- The previously introduced metrics are not normalized with regards to random labeling this means that depending on the number of samples clusters and ground truth classes a completely random labeling will not always yield the same values for homogeneity completeness and hence vmeasure In particular random labeling won’t yield zero scores especially when the number of clusters is large

This problem can safely be ignored when the number of samples is more than a thousand and the number of clusters is less than 10 For smaller sample sizes or larger number of clusters it is safer to use an adjusted index such as the Adjusted Rand Index ARI

- These metrics require the knowledge of the ground truth classes while almost never available in practice or requires manual assignment by human annotators as in the supervised learning setting

Examples

- Adjustment for chance in clustering performance evaluation Analysis of the impact of the dataset size on the value of clustering measures for random assignments

378 Chapter 3 User Guide

Mathematical formulation

Homogeneity and completeness scores are formally given by

$$h = 1 - \frac{H(C|K)}{H(K)}$$

$$c = 1 - \frac{H(K|C)}{H(K)}$$

$$V = \frac{2}{h + c}$$

where $H(K|C)$ is the conditional entropy of the classes given the cluster assignments and is given by

$$H(K|C) = -\sum_{k=1}^K \sum_{c=1}^C \frac{n_{kc}}{n} \log \frac{n_{kc}}{n}$$

$$H(K) = -\sum_{k=1}^K \frac{n_k}{n} \log \frac{n_k}{n}$$

$$H(C) = -\sum_{c=1}^C \frac{n_c}{n} \log \frac{n_c}{n}$$

$$H(K, C) = -\sum_{k=1}^K \sum_{c=1}^C \frac{n_{kc}}{n} \log \frac{n_{kc}}{n}$$

$$H(K, C) = -\sum_{k=1}^K \sum_{c=1}^C \frac{n_{kc}}{n} \log \frac{n_{kc}}{n}$$

and $H(K)$ is the entropy of the classes and is given by

$$H(K) = -\sum_{k=1}^K \frac{n_k}{n} \log \frac{n_k}{n}$$

$$H(C) = -\sum_{c=1}^C \frac{n_c}{n} \log \frac{n_c}{n}$$

$$H(K, C) = -\sum_{k=1}^K \sum_{c=1}^C \frac{n_{kc}}{n} \log \frac{n_{kc}}{n}$$

$$H(K, C) = -\sum_{k=1}^K \sum_{c=1}^C \frac{n_{kc}}{n} \log \frac{n_{kc}}{n}$$

with n the total number of samples n_k and n_c the number of samples respectively belonging to class k and cluster c

and finally n_{kc} the number of samples from class k assigned to cluster c

The conditional entropy of clusters given class k and the entropy of clusters C are defined in a symmetric manner

Rosenberg and Hirschberg further define Vmeasure as the harmonic mean of homogeneity and completeness

$$V = \frac{2}{h + c}$$

$$h = \frac{H(K|C)}{H(K)}$$

FowlkesMallows scores

The FowlkesMallows index `sklearn.metrics.fowlkesmallowsscore` can be used when the ground

truth class assignments of the samples is known The FowlkesMallows score FMI is defined as the geometric mean

of the pairwise precision and recall

FMI = $\sqrt{\frac{TP}{(TP + FP) * (TP + FN)}}$

TPFPFPFN

Where TP is the number of True Positive ie the number of pair of points that belong to the same clusters in both the

true labels and the predicted labels FP is the number of False Positive ie the number of pair of points that belong

to the same clusters in the true labels and not in the predicted labels and FN is the number of False Negative ie the

number of pair of points that belongs in the same clusters in the predicted labels and not in the true labels

The score ranges from 0 to 1 A high value indicates a good similarity between two clusters

from sklearn import metrics

labelstrue 0 0 0 1 1 1

labelspred 0 0 1 1 2 2

scikitlearn user guide Release 0213

metricsfowlkesmallowsscorelabelstrue labelspred
047140

One can permute 0 and 1 in the predicted labels rename 2 to 3 and get the same score

labelspred 1 1 0 0 3 3

metricsfowlkesmallowsscorelabelstrue labelspred
047140

Perfect labeling is scored 10

labelspred labelstrue

metricsfowlkesmallowsscorelabelstrue labelspred
10

Bad eg independent labelings have zero scores

labelstrue 0 1 2 0 3 4 5 1

labelspred 1 1 0 0 2 2 2 2

metricsfowlkesmallowsscorelabelstrue labelspred
00

Advantages

- Random uniform label assignments have a FMI score close to 00 for any value of nclusters and nsamples which is not the case for raw Mutual Information or the Vmeasure for instance
- Upperbounded at 1 Values close to zero indicate two label assignments that are largely independent while values close to one indicate significant agreement Further values of exactly 0 indicate purely independent label assignments and a FMI of exactly 1 indicates that the two label assignments are equal with or without permutation
- No assumption is made on the cluster structure can be used to compare clustering algorithms such as k means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes

Drawbacks

- Contrary to inertia FMIbased measures require the knowledge of the ground truth classes while almost never available in practice or requires manual assignment by human annotators as in the supervised learning setting

Silhouette Coefficient

If the ground truth labels are not known evaluation must be performed using the model itself The Silhouette Coefficient `sklearn.metrics.silhouette_score` is an example of such an evaluation where a higher Silhouette Coefficient score relates to a model with better defined clusters The Silhouette Coefficient is defined for each sample and is composed of two scores

- a The mean distance between a sample and all other points in the same class
- b The mean distance between a sample and all other points in the next nearest cluster

The Silhouette Coefficient `s` for a single sample is then given as

$$s = \frac{b - a}{\max(b, a)}$$

The Silhouette Coefficient for a set of samples is given as the mean of the Silhouette Coefficient for each sample

```
from sklearn import metrics
from sklearn.metrics import pairwise_distances
from sklearn import datasets
dataset = datasets.load_iris()
X = dataset.data
y = dataset.target
```

In normal usage the Silhouette Coefficient is applied to the results of a cluster analysis

```
import numpy as np
from sklearn.cluster import KMeans
kmeans_model = KMeans(n_clusters=3, random_state=1)
fit_X = kmeans_model.fit(X)
labels = kmeans_model.labels_
metricssilhouette_score(X, labels, metric=euclidean)
```

References

Advantages

- The score is bounded between -1 for incorrect clustering and 1 for highly dense clustering Scores around zero indicate overlapping clusters
- The score is higher when clusters are dense and well separated which relates to a standard concept of a cluster

Drawbacks

- The Silhouette Coefficient is generally higher for convex clusters than other concepts of clusters such as density based clusters like those obtained through DBSCAN

Examples

•Selecting the number of clusters with silhouette analysis on KMeans clustering In this example the silhouette analysis is used to choose an optimal value for nclusters

CalinskiHarabasz Index

If the ground truth labels are not known the CalinskiHarabasz index sklearnmetrics.calinskiharabaszscore also known as the Variance Ratio Criterion can be used to evaluate the model where a higher CalinskiHarabasz score relates to a model with better defined clusters

For clusters the CalinskiHarabasz score is given as the ratio of the betweenclusters dispersion mean and the withincluster dispersion

$$\frac{\text{Tr}(B)}{\text{Tr}(W)} \times \frac{1}{k-1}$$
where B is the between group dispersion matrix and W is the withincluster dispersion matrix defined by

$$B = \frac{1}{k} \sum_{k=1}^k (\bar{x}_k - \bar{x})(\bar{x}_k - \bar{x})^T$$
$$W = \sum_{k=1}^k \sum_{i \in C_k} (x_i - \bar{x}_k)(x_i - \bar{x}_k)^T$$
with n be the number of points in our data C be the set of points in cluster C be the center of cluster C be the center of C n be the number of points in cluster C

```
from sklearn import metrics
from sklearnmetrics import pairwisedistances
from sklearn import datasets
dataset = datasets.loadiris
X = dataset.data
y = dataset.target
In normal usage the CalinskiHarabasz index is applied to the results of a cluster analysis
import numpy as np
from sklearncluster import KMeans
kmeansmodel = KMeans(nclusters=3, randomstate=1).fit(X)
labels = kmeansmodel.labels
metrics.calinskiharabaszscore(X, labels)
56162
```

Advantages

- The score is higher when clusters are dense and well separated which relates to a standard concept of a cluster
- The score is fast to compute

Drawbacks

- The CalinskiHarabasz index is generally higher for convex clusters than other concepts of clusters such as density based clusters like those obtained through DBSCAN

DaviesBouldin Index

If the ground truth labels are not known the DaviesBouldin index sklearnmetrics

daviesbouldinscore can be used to evaluate the model where a lower DaviesBouldin index relates to a model with better separation between the clusters

The index is defined as the average similarity between each cluster μ_i and its most similar one μ_j In the context of this index similarity is defined as a measure $d(\mu_i, \mu_j)$ that trades off

- $d(\mu_i, \mu_j)$ the average distance between each point of cluster μ_i and the centroid of that cluster – also know as cluster diameter
- $d(\mu_i, \mu_j)$ the distance between cluster centroids μ_i and μ_j

A simple choice to construct $d(\mu_i, \mu_j)$ so that it is nonnegative and symmetric is

$$d(\mu_i, \mu_j) = \frac{1}{n_i} \sum_{x \in \mu_i} \|x - \mu_i\| + \frac{1}{n_j} \sum_{x \in \mu_j} \|x - \mu_j\|$$

Then the DaviesBouldin index is defined as

$$DB = \frac{1}{k} \sum_{i=1}^k \max_{j \neq i} \frac{d(\mu_i, \mu_j)}{\min(d(\mu_i, \mu_j), d(\mu_j, \mu_i))}$$

Zero is the lowest possible score Values closer to zero indicate a better partition

In normal usage the DaviesBouldin index is applied to the results of a cluster analysis as follows

```
from sklearn import datasets
iris = datasets.loadiris()
X = iris.data
from sklearncluster import KMeans
from sklearnmetrics import daviesbouldinscore
kmeans = KMeans(nclusters=3, randomstate=1)
fitX = kmeans.fit(X)
labels = kmeans.labels_
daviesbouldinscore(X, labels)
```

Advantages

- The computation of DaviesBouldin is simpler than that of Silhouette scores
- The index is computed only quantities and features inherent to the dataset

Drawbacks

- The DaviesBoulding index is generally higher for convex clusters than other concepts of clusters such as density based clusters like those obtained from DBSCAN
- The usage of centroid distance limits the distance metric to Euclidean space
- A good value reported by this method does not imply the best information retrieval

Contingency Matrix

Contingency matrix sklearnmetricsclustercontingencymatrix reports the intersection cardinality for every truepredicted cluster pair The contingency matrix provides sufficient statistics for all clustering metrics where the samples are independent and identically distributed and one doesn’t need to account for some instances not being clustered

Here is an example

```
from sklearnmetricscluster import contingencymatrix
x = ['a', 'a', 'b', 'b', 'b']
y = [0, 0, 1, 1, 2]
contingencymatrix(x, y)
array([[2, 1, 0],
       [0, 1, 2]])
```

The first row of output array indicates that there are three samples whose true cluster is “a” Of them two are in predicted cluster 0 one is in 1 and none is in 2 And the second row indicates that there are three samples whose true cluster is “b” Of them none is in predicted cluster 0 one is in 1 and two are in 2

A confusion matrix for classification is a square contingency matrix where the order of rows and columns correspond to a list of classes

Advantages

- Allows to examine the spread of each true cluster across predicted clusters and vice versa
- The contingency table calculated is typically utilized in the calculation of a similarity statistic like the others listed in this document between the two clusterings

Drawbacks

- Contingency matrix is easy to interpret for a small number of clusters but becomes very hard to interpret for a large number of clusters

scikitlearn user guide Release 0213

- It doesn't give a single metric to use as an objective for clustering optimisation

- Wikipedia entry for contingency matrix

324 Biclustering

Biclustering can be performed with the module `sklearn.cluster.bicluster`. Biclustering algorithms simultaneously cluster rows and columns of a data matrix. These clusters of rows and columns are known as biclusters. Each determines a submatrix of the original data matrix with some desired properties.

For instance, given a matrix of shape 10 x 10, one possible bicluster with three rows and two columns induces a submatrix of shape 3 x 2:

```
import numpy as np
data = np.arange(100).reshape(10, 10)
rows = np.array([0, 2, 3])
columns = np.array([1, 2])
data[rows, columns]
array([1, 2, 3, 12, 13, 14, 22, 23, 24, 32, 33, 34])
```

For visualization purposes, given a bicluster, the rows and columns of the data matrix may be rearranged to make the bicluster contiguous.

Algorithms differ in how they define biclusters. Some of the common types include:

- constant values (constant rows or constant columns)
- unusually high or low values
- submatrices with low variance
- correlated rows or columns

Algorithms also differ in how rows and columns may be assigned to biclusters, which leads to different bicluster structures. Block diagonal or checkerboard structures occur when rows and columns are divided into partitions. If each row and each column belongs to exactly one bicluster, then rearranging the rows and columns of the data matrix reveals the biclusters on the diagonal. Here is an example of this structure where biclusters have higher average values than the other rows and columns:

In the checkerboard case, each row belongs to all column clusters and each column belongs to all row clusters. Here is an example of this structure where the variance of the values within each bicluster is small:

After fitting a model, row and column cluster membership can be found in the `rows` and `columns` attributes:

`rows[i]` is a binary vector with nonzero entries corresponding to rows that belong to bicluster `i`. Similarly, `columns[i]` indicates which columns belong to bicluster `i`.

Some models also have `row_labels` and `column_labels` attributes. These models partition the rows and columns such as in the block diagonal and checkerboard bicluster structures.

Note: Biclustering has many other names in different fields, including `coclustering`, `two-mode clustering`, `two-way clustering`, `block clustering`, `coupled two-way clustering`, etc. The names of some algorithms, such as the Spectral CoClustering algorithm, reflect these alternate names.

scikitlearn user guide Release 0213

Fig 36 An example of checkerboard biclusters

32 Unsupervised learning 387

Spectral CoClustering

TheSpectralCoclustering algorithm finds biclusters with values higher than those in the corresponding other rows and columns Each row and each column belongs to exactly one bicluster so rearranging the rows and columns to make partitions contiguous reveals these high values along the diagonal

Note The algorithm treats the input data matrix as a bipartite graph the rows and columns of the matrix correspond to the two sets of vertices and each entry corresponds to an edge between a row and a column The algorithm approximates the normalized cut of this graph to find heavy subgraphs

Mathematical formulation

An approximate solution to the optimal normalized cut may be found via the generalized eigenvalue decomposition of the Laplacian of the graph Usually this would mean working directly with the Laplacian matrix If the original data matrix X has shape $n \times m$ the Laplacian matrix for the corresponding bipartite graph has shape $(n+m) \times (n+m)$ However in this case it is possible to work directly with X which is smaller and more efficient

The input matrix X is preprocessed as follows

$$X \leftarrow \frac{X - 12X}{\sqrt{12}}$$

Where I is the diagonal matrix with entry 1 equal to Σ

$X \leftarrow X - \frac{XX^T X}{\text{trace}(XX^T)}$ and I is the diagonal matrix with entry 1 equal to Σ

$X \leftarrow X - \frac{XX^T X}{\text{trace}(XX^T)}$

The singular value decomposition $U \Sigma V^T$ provides the partitions of the rows and columns of X A subset of the left singular vectors gives the row partitions and a subset of the right singular vectors gives the column partitions The $\lfloor \log_2 n \rfloor$ singular vectors starting from the second provide the desired partitioning information They are used to form the matrix U

$$U = \begin{bmatrix} I & 0 \\ 0 & -12I \\ 0 & -12I \end{bmatrix}$$

where the columns of U are $n/2$ $n/2$ $n/2$ and similarly for V

Then the rows of U are clustered using kmeans The first $n/2$ rows labels provide the row partitioning and the remaining $n/2$ columns labels provide the column partitioning

Examples

- A demo of the Spectral CoClustering algorithm A simple example showing how to generate a data matrix with biclusters and apply this method to it
- Biclustering documents with the Spectral Coclustering algorithm An example of finding biclusters in the twenty newsgroup dataset

References

- Dhillon Inderjit S 2001 Coclustering documents and words using bipartite spectral graph partitioning

Spectral Biclustering

TheSpectralBiclustering algorithm assumes that the input data matrix has a hidden checkerboard structure The rows and columns of a matrix with this structure may be partitioned so that the entries of any bicluster in the Cartesian product of row clusters and column clusters are approximately constant For instance if there are two row partitions and three column partitions each row will belong to three biclusters and each column will belong to two biclusters

The algorithm partitions the rows and columns of a matrix so that a corresponding blockwiseconstant checkerboard matrix provides a good approximation to the original matrix

Mathematical formulation

The input matrix X is first normalized to make the checkerboard pattern more obvious There are three possible methods

1Independent row and column normalization as in Spectral CoClustering This method makes the rows sum to a constant and the columns sum to a different constant

2Bistochastization repeated row and column normalization until convergence This method makes both rows and columns sum to the same constant

3Log normalization the log of the data matrix is computed $\log X$ Then the column mean \bar{c} row mean \bar{r} and overall mean \bar{m} of X are computed The final matrix is computed according to the formula

$$\frac{X - \bar{c} - \bar{r} + \bar{m}}{\bar{c} \bar{r}}$$

After normalizing the first few singular vectors are computed just as in the Spectral CoClustering algorithm If log normalization was used all the singular vectors are meaningful However if independent normalization or bistochastization were used the first singular vectors v_1 and w_1 are discarded From now on the “first” singular vectors refers to v_2 w_1 and v_2 w_1 except in the case of log normalization

Given these singular vectors they are ranked according to which can be best approximated by a piecewiseconstant vector The approximations for each vector are found using onedimensional kmeans and scored using the Euclidean distance Some subset of the best left and right singular vector are selected Next the data is projected to this best subset of singular vectors and clustered

For instance if k singular vectors were calculated the k best are found as described where $k = 2$ Let X be the matrix with columns the k best left singular vectors and similarly Y for the right To partition the rows the rows of X are projected to a k dimensional space XY Treating the k rows of this $k \times k$ matrix as samples and clustering using kmeans yields the row labels Similarly projecting the columns to $Y^T X$ and clustering this $k \times k$ matrix yields the column labels

Examples

•A demo of the Spectral Biclustering algorithm a simple example showing how to generate a checkerboard matrix and bicluster it

References

- Kluger Yuval et al 2003 Spectral biclustering of microarray data coclustering genes and conditions

Biclustering evaluation

There are two ways of evaluating a biclustering result internal and external Internal measures such as cluster stability rely only on the data and the result themselves Currently there are no internal bicluster measures in scikit learn External measures refer to an external source of information such as the true solution When working with real data the true solution is usually unknown but biclustering artificial data may be useful for evaluating algorithms precisely because the true solution is known

To compare a set of found biclusters to the set of true biclusters two similarity measures are needed a similarity measure for individual biclusters and a way to combine these individual similarities into an overall score

To compare individual biclusters several measures have been used For now only the Jaccard index is implemented

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|}$$

$$J(A, B) = \frac{|A \cap B|}{|A| + |B| - |A \cap B|}$$

where A and B are biclusters $|A \cap B|$ is the number of elements in their intersection The Jaccard index achieves its minimum of 0 when the biclusters do not overlap at all and its maximum of 1 when they are identical

Several methods have been developed to compare two sets of biclusters For now only consensus_score Hochreiter et al 2010 is available

1 Compute bicluster similarities for pairs of biclusters one in each set using the Jaccard index or a similar measure

2 Assign biclusters from one set to another in a one-to-one fashion to maximize the sum of their similarities This step is performed using the Hungarian algorithm

3 The final sum of similarities is divided by the size of the larger set

The minimum consensus score 0 occurs when all pairs of biclusters are totally dissimilar The maximum score 1 occurs when both sets are identical

325 Decomposing signals in components matrix factorization problems

Principal component analysis PCA (Principal Component Analysis)

Exact PCA (Principal Component Analysis) and probabilistic interpretation

PCA (Principal Component Analysis) is used to decompose a multivariate dataset in a set of successive orthogonal components that explain a maximum amount of the variance In scikitlearn PCA (Principal Component Analysis) is implemented as a transformer object that learns k components in its fit method and can be used on new data to project it on these components

PCA (Principal Component Analysis) centers but does not scale the input data for each feature before applying the SVD The optional parameter `whiten=True` makes it possible to project the data onto the singular space while scaling each component to unit variance This is often useful if the models downstream make strong assumptions on the isotropy of the signal

this is for example the case for Support Vector Machines with the RBF (Radial Basis Function) kernel and the KMeans clustering algorithm Below is an example of the iris dataset which is comprised of 4 features projected on the 2 dimensions that explain most variance

The PCA object also provides a probabilistic interpretation of the PCA (Principal Component Analysis) that can give a likelihood of data based on the amount of variance it explains As such it implements a score method that can be used in crossvalidation

Examples

- Comparison of LDA and PCA (Principal Component Analysis) 2D projection of Iris dataset
- Model selection with Probabilistic PCA (Principal Component Analysis) and Factor Analysis FA

Incremental PCA (Principal Component Analysis)

ThePCA object is very useful but has certain limitations for large datasets The biggest limitation is that PCA (Principal Component Analysis) only supports batch processing which means all of the data to be processed must fit in main memory The IncrementalPCA object uses a different form of processing and allows for partial computations which almost exactly match the results ofPCA while processing the data in a minibatch fashion IncrementalPCA makes it possible to implement outof core Principal Component Analysis either by

- Using its partialfit method on chunks of data fetched sequentially from the local hard drive or a network database
- Calling its fit method on a memory mapped file using numpymemmap

IncrementalPCA only stores estimates of component and noise variances in order update explainedvarianceratio incrementally This is why memory usage depends on the number of samples per batch rather than the number of samples to be processed in the dataset

As inPCAIncrementalPCA centers but does not scale the input data for each feature before applying the SVD

Examples

- Incremental PCA (Principal Component Analysis)

PCA (Principal Component Analysis) using randomized SVD

It is often interesting to project data to a lowerdimensional space that preserves most of the variance by dropping the singular vector of components associated with lower singular values

For instance if we work with 64x64 pixel graylevel pictures for face recognition the dimensionality of the data is 4096 and it is slow to train an RBF (Radial Basis Function) support vector machine on such wide data Furthermore we know that the intrinsic dimensionality of the data is much lower than 4096 since all pictures of human faces look somewhat alike The samples lie on a manifold of much lower dimension say around 200 for instance The PCA (Principal Component Analysis) algorithm can be used to linearly transform the data while both reducing the dimensionality and preserve most of the explained variance at the same time

The classPCA used with the optional parameter svdsolverrandomized is very useful in that case since we are going to drop most of the singular vectors it is much more efficient to limit the computation to an approximated estimate of the singular vectors we will keep to actually perform the transform

For instance the following shows 16 sample portraits centered around 00 from the Olivetti dataset On the right hand side are the first 16 singular vectors reshaped as portraits Since we only require the top 16 singular vectors of a dataset with size 400 and 64x64 4096 the computation time is less than 1s

scikitlearn user guide Release 0213

If we note $\max \max \text{samples} \text{ features}$ and $\min \min \text{samples} \text{ features}$ the time complexity of the randomizedPCA is $O(n^2)$

$\max \cdot \text{components}$ instead of $O(n^2)$

$\max \cdot \min$ for the exact method implemented in PCA (Principal Component Analysis)

The memory footprint of randomized PCA (Principal Component Analysis) is also proportional to $2 \cdot \max \cdot \text{components}$ instead of $\max \cdot \min$ for the exact method

Note the implementation of `inverse_transform` in PCA with `svd_solver='randomized'` is not the exact

inverse transform of `transform` even when `whiten=False` default

Examples

- Faces recognition example using eigenfaces and SVMs
- Faces dataset decompositions

References

- “Finding structure with randomness Stochastic algorithms for constructing approximate matrix decompositions” Halko et al 2009

Kernel PCA (Principal Component Analysis)

KernelPCA is an extension of PCA (Principal Component Analysis) which achieves nonlinear dimensionality reduction through the use of kernels see Pairwise metrics Affinities and Kernels It has many applications including denoising compression and structured prediction kernel dependency estimation KernelPCA supports both transform and inversetransform

Examples

- Kernel PCA (Principal Component Analysis)

Sparse principal components analysis SparsePCA and MiniBatchSparsePCA

SparsePCA is a variant of PCA (Principal Component Analysis) with the goal of extracting the set of sparse components that best reconstruct the data

Minibatch sparse PCA (Principal Component Analysis) MiniBatchSparsePCA is a variant of SparsePCA that is faster but less accurate The increased speed is reached by iterating over small chunks of the set of features for a given number of iterations

Principal component analysis PCA (Principal Component Analysis) has the disadvantage that the components extracted by this method have exclusively dense expressions ie they have nonzero coefficients when expressed as linear combinations of the original variables This can make interpretation difficult In many cases the real underlying components can be more naturally imagined as sparse vectors for example in face recognition components might naturally map to parts of faces

Sparse principal components yields a more parsimonious interpretable representation clearly emphasizing which of the original features contribute to the differences between samples

The following example illustrates 16 components extracted using sparse PCA (Principal Component Analysis) from the Olivetti faces dataset It can be seen how the regularization term induces many zeros Furthermore the natural structure of the data causes the nonzero coefficients to be vertically adjacent The model does not enforce this mathematically each component is

scikitlearn user guide Release 0213

a vector $h \in \mathbb{R}^{4096}$ and there is no notion of vertical adjacency except during the humanfriendly visualization as 64x64 pixel images The fact that the components shown below appear local is the effect of the inherent structure of the data which makes such local patterns minimize reconstruction error There exist sparsityinducing norms that take into account adjacency and different kinds of structure see Jen09 for a review of such methods For more details on how to use Sparse PCA (Principal Component Analysis) see the Examples section below

Note that there are many different formulations for the Sparse PCA (Principal Component Analysis) problem The one implemented here is based on MrI09 The optimization problem solved is a PCA (Principal Component Analysis) problem dictionary learning with an ℓ_1 penalty on the components

$$\begin{aligned} & \arg \min_{W, A} \|W\|_1 \\ & \|W\|_1 - \|A\|_2^2 \\ & \|A\|_1 \end{aligned}$$

subject to $\|A\|_2 \leq 1$ for all $0 \leq i \leq n$

The sparsityinducing ℓ_1 norm also prevents learning components from noise when few training samples are available The degree of penalization and thus sparsity can be adjusted through the hyperparameter alpha Small values lead to a gently regularized factorization while larger values shrink many coefficients to zero

Note While in the spirit of an online algorithm the class MiniBatchSparsePCA does not implement partialfit because the algorithm is online along the features direction not the samples direction

Examples

- Faces dataset decompositions

Truncated singular value decomposition and latent semantic analysis

TruncatedSVD implements a variant of singular value decomposition SVD that only computes the σ largest singular values where σ is a userspecified parameter

When truncated SVD is applied to termdocument matrices as returned by CountVectorizer or

TfidfVectorizer this transformation is known as latent semantic analysis LSA because it transforms such

matrices to a “semantic” space of low dimensionality In particular LSA is known to combat the effects of synonymy

and polysemy both of which roughly mean there are multiple meanings per word which cause termdocument ma

trices to be overly sparse and exhibit poor similarity under measures such as cosine similarity

Note LSA is also known as latent semantic indexing LSI though strictly that refers to its use in persistent indexes

for information retrieval purposes

Mathematically truncated SVD applied to training samples X produces a lowrank approximation \hat{X}

$$\hat{X} \approx U \Sigma V^T$$

U

After this operation $U \Sigma V^T$

\hat{X} is the transformed training set with σ features called ncomponents in the API (Application Programming Interface)

To also transform a test set X_{test} we multiply it with U

$$\hat{X}_{test} = U X_{test}$$

Note Most treatments of LSA in the natural language processing NLP and information retrieval IR literature

swap the axes of the matrix X so that it has shape nfeatures x nsamples We present LSA in a different way

that matches the scikitlearn API (Application Programming Interface) better but the singular values found are the same

TruncatedSVD is very similar to PCA (Principal Component Analysis) but differs in that it works on sample matrices X directly instead of their

covariance matrices When the columnwise perfeature means of X are subtracted from the feature values truncated

SVD on the resulting matrix is equivalent to PCA (Principal Component Analysis) In practical terms this means that the TruncatedSVD transformer

acceptsscipysparse matrices without the need to densify them as densifying may fill up memory even for

mediumsized document collections

While theTruncatedSVD transformer works with any sparse feature matrix using it on tf-idf matrices is recom

mended over raw frequency counts in an LSAdocument processing setting In particular sublinear scaling and inverse

document frequency should be turned on sublineartf=True useidf=True to bring the feature values

closer to a Gaussian distribution compensating for LSA’s erroneous assumptions about textual data

Examples

- Clustering text documents using kmeans

Dictionary Learning

Sparse coding with a precomputed dictionary

TheSparseCoder object is an estimator that can be used to transform signals into sparse linear combination of atoms from a fixed precomputed dictionary such as a discrete wavelet basis This object therefore does not implement afit method The transformation amounts to a sparse coding problem finding a representation of the data as a linear combination of as few dictionary atoms as possible All variations of dictionary learning implement the following transform methods controllable via the transformmethod initialization parameter

- Orthogonal matching pursuit Orthogonal Matching Pursuit OMP
- Leastangle regression Least Angle Regression
- Lasso computed by leastangle regression
- Lasso using coordinate descent Lasso
- Thresholding

Thresholding is very fast but it does not yield accurate reconstructions They have been shown useful in literature for classification tasks For image reconstruction tasks orthogonal matching pursuit yields the most accurate unbiased reconstruction

The dictionary learning objects offer via the splitcode parameter the possibility to separate the positive and negative values in the results of sparse coding This is useful when dictionary learning is used for extracting features that will be used for supervised learning because it allows the learning algorithm to assign different weights to negative loadings of a particular atom from to the corresponding positive loading

The split code for a single sample has length 2ncomponents and is constructed using the following rule First the regular code of length ncomponents is computed Then the first ncomponents entries of the splitcode are filled with the positive part of the regular code vector The second half of the split code is filled with the negative part of the code vector only with a positive sign Therefore the splitcode is nonnegative

Examples

- Sparse coding with a precomputed dictionary

Generic dictionary learning

Dictionary learning DictionaryLearning is a matrix factorization problem that amounts to finding a usually overcomplete dictionary that will perform well at sparsely encoding the fitted data

Representing data as sparse combinations of atoms from an overcomplete dictionary is suggested to be the way the mammalian primary visual cortex works Consequently dictionary learning applied on image patches has been shown to give good results in image processing tasks such as image completion inpainting and denoising as well as for supervised recognition tasks

Dictionary learning is an optimization problem solved by alternatively updating the sparse code as a solution to multiple Lasso problems considering the dictionary fixed and then updating the dictionary to best fit the sparse code

$$\begin{aligned} & \arg \min_{\mathbf{C}} \|\mathbf{C}\|_1 \\ & \frac{1}{2} \|\mathbf{X} - \mathbf{D}\mathbf{C}\|_2^2 \\ & \text{subject to } \|\mathbf{c}_i\|_2 \leq 1 \text{ for all } 0 \leq i < \text{atoms} \end{aligned}$$

After using such a procedure to fit the dictionary the transform is simply a sparse coding step that shares the same implementation with all dictionary learning objects see Sparse coding with a precomputed dictionary
It is also possible to constrain the dictionary and/or code to be positive to match constraints that may be present in the data Below are the faces with different positivity constraints applied Red indicates negative values blue indicates positive values and white represents zeros

scikitlearn user guide Release 0213

The following image shows how a dictionary learned from 4x4 pixel image patches extracted from part of the image of a raccoon face looks like

Examples

Minibatch dictionary learning

MiniBatchDictionaryLearning implements a faster but less accurate version of the dictionary learning algorithm that is better suited for large datasets

By default MiniBatchDictionaryLearning divides the data into minibatches and optimizes in an online manner by cycling over the minibatches for the specified number of iterations However at the moment it does not implement a stopping condition

scikitlearn user guide Release 0213

The estimator also implements `partialfit` which updates the dictionary by iterating only once over a minibatch. This can be used for online learning when the data is not readily available from the start or for when the data does not fit into the memory.

Clustering for dictionary learning

Note that when using dictionary learning to extract a representation eg for sparse coding clustering can be a good proxy to learn the dictionary. For instance the `MiniBatchKMeans` estimator is computationally efficient and implements online learning with a `partialfit` method.

Example Online learning of a dictionary of parts of faces

Factor Analysis

In unsupervised learning we only have a dataset $X \in \mathbb{R}^{n \times 2}$. How can this dataset be described mathematically? A very simple continuous latent variable model for X is

$$X = h\epsilon$$

The vector h is called “latent” because it is unobserved. ϵ is considered a noise term distributed according to a Gaussian with mean 0 and covariance Σ . μ is some arbitrary offset vector. Such a model is called “generative” as it describes how X is generated from h . If we use all the h ’s as columns to form a matrix H and all the ϵ ’s as columns of a matrix E then we can write with suitably defined M and ϵ

$$X = H\epsilon$$

In other words we decomposed matrix X

If h is given the above equation automatically implies the following probabilistic interpretation

$$X = h\epsilon$$

For a complete probabilistic model we also need a prior distribution for the latent variable h . The most straightforward assumption based on the nice properties of the Gaussian distribution is $h \sim \mathcal{N}(0, I)$. This yields a Gaussian as the marginal distribution of X

$$X \sim \mathcal{N}(\mu, \Sigma)$$

Now without any further assumptions the idea of having a latent variable h would be superfluous – X can be completely modelled with a mean and a covariance. We need to impose some more specific structure on one of these two parameters. A simple additional assumption regards the structure of the error covariance Σ

• $\Sigma = I$! This assumption leads to the probabilistic model of PCA (Principal Component Analysis)

scikitlearn user guide Release 0213

• $\Sigma = \text{diag}(\sigma_1^2, \sigma_2^2, \dots, \sigma_p^2)$ This model is called FactorAnalysis a classical statistical model The matrix W is sometimes called the “factor loading matrix”

Both models essentially estimate a Gaussian with a lowrank covariance matrix Because both models are probabilistic they can be integrated in more complex models eg Mixture of Factor Analysers One gets very different models eg FastICA if nonGaussian priors on the latent variables are assumed

Factor analysis can produce similar components the columns of its loading matrix to PCA (Principal Component Analysis) However one can not make any general statements about these components eg whether they are orthogonal The main advantage for Factor Analysis over PCA (Principal Component Analysis) is that it can model the variance in every direction of the input space independently heteroscedastic noise

This allows better model selection than probabilistic PCA (Principal Component Analysis) in the presence of heteroscedastic noise Examples

• Model selection with Probabilistic PCA (Principal Component Analysis) and Factor Analysis FA

Independent component analysis ICA

Independent component analysis separates a multivariate signal into additive subcomponents that are maximally independent It is implemented in scikitlearn using the Fast ICA algorithm Typically ICA is not used for reducing dimensionality but for separating superimposed signals Since the ICA model does not include a noise term for the model to be correct whitening must be applied This can be done internally using the `whiten` argument or manually using one of the PCA (Principal Component Analysis) variants

It is classically used to separate mixed signals a problem known as blind source separation as in the example below ICA can also be used as yet another non linear decomposition that finds components with some sparsity

scikitlearn user guide Release 0213

Examples

- Blind source separation using FastICA
- FastICA on 2D point clouds
- Faces dataset decompositions

Nonnegative matrix factorization NMF (Non-Negative Matrix Factorization) or NNMF

NMF (Non-Negative Matrix Factorization) with the Frobenius norm

NMF is an alternative approach to decomposition that assumes that the data and the components are nonnegative

NMF (Non-Negative Matrix Factorization) can be plugged in instead of PCA (Principal Component Analysis) or its variants in the cases where the data values are nonnegative. It finds a decomposition of samples X into two matrices W and H of nonnegative elements by optimizing the distance between X and the matrix product WH . The most widely used distance function is the squared Frobenius norm which is an obvious extension of the Euclidean norm to matrices

$$\|X - WH\|_F^2 = \sum_{i,j} (X_{ij} - \sum_k W_{ik} H_{kj})^2$$

$$\|X - WH\|_F^2 = \sum_{i,j} X_{ij}^2 - 2 \sum_{i,j,k} X_{ij} W_{ik} H_{kj} + \sum_{i,j,k,l} W_{ik} H_{kj} W_{il} H_{lj}$$

$$\|X - WH\|_F^2 = \sum_{i,j} X_{ij}^2 - 2 \sum_{i,j,k} X_{ij} W_{ik} H_{kj} + \sum_{i,j,k,l} W_{ik} H_{kj} W_{il} H_{lj}$$

$$\|X - WH\|_F^2 = \sum_{i,j} X_{ij}^2 - 2 \sum_{i,j,k} X_{ij} W_{ik} H_{kj} + \sum_{i,j,k,l} W_{ik} H_{kj} W_{il} H_{lj}$$

$$\|X - WH\|_F^2 = \sum_{i,j} X_{ij}^2 - 2 \sum_{i,j,k} X_{ij} W_{ik} H_{kj} + \sum_{i,j,k,l} W_{ik} H_{kj} W_{il} H_{lj}$$

Unlike PCA the representation of a vector is obtained in an additive fashion by superimposing the components without subtracting. Such additive models are efficient for representing images and text.

It has been observed in Hoyer 2004 that when carefully constrained NMF (Non-Negative Matrix Factorization) can produce a parts-based representation of the dataset resulting in interpretable models. The following example displays 16 sparse components found by NMF (Non-Negative Matrix Factorization) from the images in the Olivetti faces dataset in comparison with the PCA (Principal Component Analysis) eigenfaces.

2 “Nonnegative Matrix Factorization with Sparseness Constraints” P Hoyer 2004

32 Unsupervised learning 407

The `init` attribute determines the initialization method applied which has a great impact on the performance of the method. `NMF` implements the method Nonnegative Double Singular Value Decomposition. `NNDSVD` is based on two SVD processes: one approximating the data matrix, the other approximating positive sections of the resulting partial SVD factors, utilizing an algebraic property of unit rank matrices. The basic `NNDSVD` algorithm is better fit for sparse factorization. Its variants `NNDSVDa` in which all zeros are set equal to the mean of all elements of the data, and `NNDSVDar` in which the zeros are set to random perturbations less than the mean of the data divided by 100 are recommended in the dense case.

Note that the Multiplicative Update ‘`mu`’ solver cannot update zeros present in the initialization so it leads to poorer results when used jointly with the basic `NNDSVD` algorithm which introduces a lot of zeros in this case. `NNDSVDa` or `NNDSVDar` should be preferred.

`NMF` (Non-Negative Matrix Factorization) can also be initialized with correctly scaled random nonnegative matrices by setting `init='random'`. An integer seed or a `RandomState` can also be passed to `random_state` to control reproducibility.

In `NMF`, L1 and L2 priors can be added to the loss function in order to regularize the model. The L2 prior uses the Frobenius norm while the L1 prior uses an elementwise L1 norm. As in `ElasticNet`, we control the combination of L1 and L2 with the `l1_ratio` parameter and the intensity of the regularization with the `alpha` parameter.

Then the priors terms are

$$\frac{\alpha}{2} \|W\|_1 + \frac{\beta}{2} \|H\|_1 - \langle W, H \rangle$$

$$\frac{\alpha}{2} \|W\|_2^2$$

$$\frac{\beta}{2} \|H\|_2^2$$

$$\frac{\alpha}{2} \|W\|_2^2$$

$$\frac{\beta}{2} \|H\|_2^2$$

4 “SVD based initialization: A head start for nonnegative matrix factorization” C. Boutsidis, E. Gallopoulos, 2008

scikitlearn user guide Release 0213
and the regularized objective function is

$$\frac{1}{2} \|W - WH\|_F^2 + \frac{\lambda}{2} \|W\|_F^2 + \frac{\lambda}{2} \|H\|_F^2$$

NMF (Non-Negative Matrix Factorization) regularizes both W and H The public function nonnegativefactorization allows a finer control through the regularization attribute and may regularize only W only H or both

NMF (Non-Negative Matrix Factorization) with a betadivergence

As described previously the most widely used distance function is the squared Frobenius norm which is an obvious extension of the Euclidean norm to matrices

$$\frac{1}{2} \|W - WH\|_F^2 + \frac{\lambda}{2} \|W\|_F^2 + \frac{\lambda}{2} \|H\|_F^2$$

Other distance functions can be used in NMF (Non-Negative Matrix Factorization) as for example the generalized KullbackLeibler KL divergence also referred as Idivergence

$$\sum_i \left(\frac{W_{ij}}{WH_{ij}} \log \frac{W_{ij}}{WH_{ij}} \right)$$

Or the ItakuraSaito IS divergence

$$\sum_i \left(\frac{W_{ij}}{WH_{ij}} - \log \frac{W_{ij}}{WH_{ij}} - 1 \right)$$

These three distances are special cases of the betadivergence family with $\beta = 2, 1, 0$ respectively The beta divergence are defined by

$$\sum_i \left(\frac{W_{ij}}{WH_{ij}} - 1 + \frac{1}{\beta} \left(\frac{W_{ij}}{WH_{ij}} - 1 \right)^\beta \right)$$

Note that this definition is not valid if $\beta \in [0, 1]$ yet it can be continuously extended to the definitions of $\beta = 0$ and $\beta = 1$ respectively

NMF (Non-Negative Matrix Factorization) implements two solvers using Coordinate Descent ‘cd’ and Multiplicative Update ‘mu’ The ‘mu’ solver can optimize every betadivergence including of course the Frobenius norm $\beta = 2$ the generalized Kullback Leibler divergence $\beta = 1$ and the ItakuraSaito divergence $\beta = 0$ Note that for $\beta \in [1, 2]$ the ‘mu’ solver is significantly faster than for other values of β Note also that with a negative or 0 ie ‘itakurasaito’ the input matrix cannot contain zero values

The ‘cd’ solver can only optimize the Frobenius norm Due to the underlying nonconvexity of NMF (Non-Negative Matrix Factorization) the different solvers may converge to different minima even when optimizing the same distance function

NMF (Non-Negative Matrix Factorization) is best used with the fittransform method which returns the matrix W The matrix H is stored into the fitted model in the components attribute the method transform will decompose a new matrix Xnew based on these stored components

```
import numpy as np
X = np.array([1, 2, 1, 3, 12, 4, 1, 5, 08, 6, 1])
from sklearn.decomposition import NMF (Non-Negative Matrix Factorization)
model = NMF(n_components=2, init='random', random_state=0)
```

Latent Dirichlet Allocation LDA

Latent Dirichlet Allocation is a generative probabilistic model for collections of discrete dataset such as text corpora

It is also a topic model that is used for discovering abstract topics from a collection of documents

The graphical model of LDA is a threelevel generative model

410 Chapter 3 User Guide

Note on notations presented in the graphical model above which can be found in Hoffman et al 2013

- The corpus is a collection of D documents
- A document is a sequence of N words
- There are K topics in the corpus
- The boxes represent repeated sampling

In the graphical model each node is a random variable and has a role in the generative process A shaded node indicates an observed variable and an unshaded node indicates a hidden latent variable In this case words in the corpus are the only data that we observe The latent variables determine the random mixture of topics in the corpus and the distribution of words in the documents The goal of LDA is to use the observed words to infer the hidden topic structure

When modeling text corpora the model assumes the following generative process for a corpus with D documents and K topics with V corresponding to n components in the API (Application Programming Interface)

- 1 For each topic $k \in K$ draw $\theta_k \sim \text{Dirichlet}(\alpha)$ This provides a distribution over the words ie the probability of a word appearing in topic k corresponds to θ_k
- 2 For each document $d \in D$ draw the topic proportions $\phi_d \sim \text{Dirichlet}(\beta)$ corresponds to ϕ_d

3 For each word n in document d

- 1 Draw the topic assignment $z_n \sim \text{Multinomial}(\phi_d)$
- 2 Draw the observed word $w_n \sim \text{Multinomial}(\theta_{z_n})$

For parameter estimation the posterior distribution is

$$p(\theta, \phi, z | w) \propto \prod_{k=1}^K \Gamma(\alpha) \prod_{v=1}^V \theta_{kv}^{\alpha_{kv} - 1} \prod_{d=1}^D \Gamma(\beta) \prod_{v=1}^V \phi_{dv}^{\beta_{dv} - 1} \prod_{n=1}^N \Gamma(\theta_{z_n, w_n}) \theta_{z_n, w_n}$$

Since the posterior is intractable variational Bayesian method uses a simpler distribution $q(\theta, \phi, z)$ to approximate it and those variational parameters are optimized to maximize the Evidence Lower Bound ELBO

$$\log p(w) \geq \mathbb{E}_{q(\theta, \phi, z)} [\log p(w | \theta, \phi, z)] - \text{KL}(q(\theta, \phi, z) || p(\theta, \phi, z))$$

Maximizing ELBO is equivalent to minimizing the KullbackLeiblerKL divergence between $q(\theta, \phi, z)$ and the true posterior $p(\theta, \phi, z | w)$

LatentDirichletAllocation implements the online variational Bayes algorithm and supports both online and batch update methods While the batch method updates variational variables after each full pass through the data the online method updates variational variables from minibatch data points

Note Although the online method is guaranteed to converge to a local optimum point the quality of the optimum point and the speed of convergence may depend on minibatch size and attributes related to learning rate setting

scikitlearn user guide Release 0213

WhenLatentDirichletAllocation is applied on a “documentterm” matrix the matrix will be decomposed into a “topicterm” matrix and a “documenttopic” matrix While “topicterm” matrix is stored as components in the model “documenttopic” matrix can be calculated from transform method LatentDirichletAllocation also implements partialfit method This is used when data can be fetched sequentially

326 Covariance estimation

Many statistical problems require the estimation of a population’s covariance matrix which can be seen as an estimation of data set scatter plot shape Most of the time such an estimation has to be done on a sample whose properties size structure homogeneity have a large influence on the estimation’s quality The sklearncovariance package provides tools for accurately estimating a population’s covariance matrix under various settings We assume that the observations are independent and identically distributed iid

Empirical covariance

The covariance matrix of a data set is known to be well approximated by the classical maximum likelihood estimator or “empirical covariance” provided the number of observations is large enough compared to the number of features the variables describing the observations More precisely the Maximum Likelihood Estimator of a sample is an unbiased estimator of the corresponding population’s covariance matrix

The empirical covariance matrix of a sample can be computed using the empiricalcovariance function of the package or by fitting an EmpiricalCovariance object to the data sample with the EmpiricalCovariance fit method Be careful that results depend on whether the data are centered so one may want to use the assumecentered parameter accurately More precisely if assumecenteredFalse then the test set is supposed to have the same mean vector as the training set If not both should be centered by the user and assumecenteredTrue should be used

Examples

- See Shrinkage covariance estimation LedoitWolf vs OAS and maxlikelihood for an example on how to fit an EmpiricalCovariance object to data

Shrunk Covariance

Basic shrinkage

Despite being an unbiased estimator of the covariance matrix the Maximum Likelihood Estimator is not a good estimator of the eigenvalues of the covariance matrix so the precision matrix obtained from its inversion is not accurate. Sometimes it even occurs that the empirical covariance matrix cannot be inverted for numerical reasons. To avoid such an inversion problem a transformation of the empirical covariance matrix has been introduced: the shrinkage. In scikitlearn this transformation with a userdefined shrinkage coefficient can be directly applied to a precomputed covariance with the `shrunkcovariance` method. Also a shrunk estimator of the covariance can be fitted to data with a `ShrunkCovariance` object and its `ShrunkCovariancefit` method. Again results depend on whether the data are centered so one may want to use the `assume_centered` parameter accurately.

Mathematically this shrinkage consists in reducing the ratio between the smallest and the largest eigenvalues of the empirical covariance matrix. It can be done by simply shifting every eigenvalue according to a given offset which is equivalent of finding the L_2 penalized Maximum Likelihood Estimator of the covariance matrix. In practice shrinkage boils down to a simple convex transformation $\hat{\Sigma}_{shrunk} = (1 - \alpha) \hat{\Sigma} + \alpha \text{Tr}(\hat{\Sigma}) / d$

Choosing the amount of shrinkage amounts to setting a biasvariance tradeoff and is discussed below.

- Examples
- See Shrinkage covariance estimation: LedoitWolf vs OAS and maxlikelihood for an example on how to fit a `ShrunkCovariance` object to data.

LedoitWolf shrinkage

In their 2004 paper¹ O Ledoit and M Wolf propose a formula to compute the optimal shrinkage coefficient α that minimizes the Mean Squared Error between the estimated and the real covariance matrix. The `LedoitWolf` estimator of the covariance matrix can be computed on a sample with the `ledoitwolf` function of the `sklearn.covariance` package or it can be otherwise obtained by fitting a `LedoitWolf` object to the same sample.

Note: Case when population covariance matrix is isotropic

It is important to note that when the number of samples is much larger than the number of features one would expect that no shrinkage would be necessary. The intuition behind this is that if the population covariance is full rank when the number of samples grows the sample covariance will also become positive definite. As a result no shrinkage would be necessary and the method should automatically do this.

This however is not the case in the `LedoitWolf` procedure when the population covariance happens to be a multiple of the identity matrix. In this case the `LedoitWolf` shrinkage estimate approaches 1 as the number of samples increases. This indicates that the optimal estimate of the covariance matrix in the `LedoitWolf` sense is multiple of the identity. Since the population covariance is already a multiple of the identity matrix the `LedoitWolf` solution is indeed a reasonable estimate.

Oracle Approximating Shrinkage

Under the assumption that the data are Gaussian distributed Chen et al² derived a formula aimed at choosing a shrinkage coefficient that yields a smaller Mean Squared Error than the one given by Ledoit and Wolf’s formula The resulting estimator is known as the Oracle Shrinkage Approximating estimator of the covariance

The OAS estimator of the covariance matrix can be computed on a sample with the oas function of the sklearn covariance package or it can be otherwise obtained by fitting an OAS object to the same sample

Sparse inverse covariance

The matrix inverse of the covariance matrix often called the precision matrix is proportional to the partial correlation matrix It gives the partial independence relationship In other words if two features are independent conditionally on the others the corresponding coefficient in the precision matrix will be zero This is why it makes sense to estimate a sparse precision matrix the estimation of the covariance matrix is better conditioned by learning independence relations from the data This is known as covariance selection

In the smallsamples situation in which nsamples is on the order of nfeatures or smaller sparse inverse covariance estimators tend to work better than shrunk covariance estimators However in the opposite situation or for very correlated data they can be numerically unstable In addition unlike shrinkage estimators sparse estimators are able to recover offdiagonal structure

TheGraphicalLasso estimator uses an l1 penalty to enforce sparsity on the precision matrix the higher its alpha parameter the more sparse the precision matrix The corresponding GraphicalLassoCV object uses crossvalidation to automatically set the alpha parameter

Note Structure recovery

Recovering a graphical structure from correlations in the data is a challenging thing If you are interested in such recovery keep in mind that

- Recovery is easier from a correlation matrix than a covariance matrix standardize your observations before runningGraphicalLasso
- If the underlying graph has nodes with much more connections than the average node the algorithm will miss some of these connections

scikitlearn user guide Release 0213

Fig 38 A comparison of maximum likelihood shrinkage and sparse estimates of the covariance and precision matrix in the very small samples settings

- If your number of observations is not large compared to the number of edges in your underlying graph you will not recover it
- Even if you are in favorable recovery conditions the alpha parameter chosen by crossvalidation eg using the GraphicalLassoCV object will lead to selecting too many edges However the relevant edges will have heavier weights than the irrelevant ones

The mathematical formulation is the following

$$\hat{\Sigma} = \operatorname{argmin}_{\Sigma} \left\{ \operatorname{tr}(\Sigma S) - \log \det \Sigma + \lambda \|\Sigma\|_1 \right\}$$

Where Σ is the precision matrix to be estimated and S is the sample covariance matrix $\|\Sigma\|_1$ is the sum of the absolute values of offdiagonal coefficients of Σ The algorithm employed to solve this problem is the GLasso algorithm from the Friedman 2008 Biostatistics paper It is the same algorithm as in the R glasso package

Robust Covariance Estimation

Real data sets are often subject to measurement or recording errors Regular but uncommon observations may also appear for a variety of reasons Observations which are very uncommon are called outliers The empirical covariance estimator and the shrunk covariance estimators presented above are very sensitive to the presence of outliers in the data Therefore one should use robust covariance estimators to estimate the covariance of its real data sets Alternatively robust covariance estimators can be used to perform outlier detection and discarddownweight some observations according to further processing of the data

Thesklearncovariance package implements a robust estimator of covariance the Minimum Covariance De terminant3

Minimum Covariance Determinant

The Minimum Covariance Determinant estimator is a robust estimator of a data set’s covariance introduced by PJ Rousseeuw in3 The idea is to find a given proportion h of “good” observations which are not outliers and compute their empirical covariance matrix This empirical covariance matrix is then rescaled to compensate the performed selection of observations “consistency step” Having computed the Minimum Covariance Determinant estimator one can give weights to observations according to their Mahalanobis distance leading to a reweighted estimate of the covariance matrix of the data set “reweighting step”

Rousseeuw and Van Driessen4developed the FastMCD algorithm in order to compute the Minimum Covariance Determinant This algorithm is used in scikitlearn when fitting an MCD object to data The FastMCD algorithm also computes a robust estimate of the data set location at the same time

Raw estimates can be accessed as rawlocation andrawcovariance attributes of a MinCovDet robust covariance estimator object

References

Examples

Influence of outliers on location and covariance

estimatesSeparating inliers from outliers using a Mahalanobis distance

327 Novelty and Outlier Detection

Many applications require being able to decide whether a new observation belongs to the same distribution as existing observations it is an inlier or should be considered as different it is an outlier Often this ability is used to clean real data sets Two important distinctions must be made

outlier detection The training data contains outliers which are defined as observations that are far from the others Outlier detection estimators thus try to fit the regions where the training data is the most concentrated ignoring the deviant observations

novelty detection The training data is not polluted by outliers and we are interested in detecting whether anew observation is an outlier In this context an outlier is also called a novelty

Outlier detection and novelty detection are both used for anomaly detection where one is interested in detecting abnormal or unusual observations Outlier detection is then also known as unsupervised anomaly detection and novelty detection as semisupervised anomaly detection In the context of outlier detection the outliersanomalies cannot form a dense cluster as available estimators assume that the outliersanomalies are located in low density regions On the contrary in the context of novelty detection noveltiesanomalies can form a dense cluster as long as they are in a low density region of the training data considered as normal in this context

The scikitlearn project provides a set of machine learning tools that can be used both for novelty or outlier detection This strategy is implemented with objects learning in an unsupervised way from the data

estimatorfitXtrain

new observations can then be sorted as inliers or outliers with a predict method

estimatorpredictXtest

Inliers are labeled 1 while outliers are labeled 1 The predict method makes use of a threshold on the raw scoring function computed by the estimator This scoring function is accessible through the scoresamples method while the threshold can be controlled by the contamination parameter

Thedecisionfunction method is also defined from the scoring function in such a way that negative values are outliers and nonnegative ones are inliers

estimatordecisionfunctionXtest

418 Chapter 3 User Guide

scikitlearn user guide Release 0213

Note that neighborsLocalOutlierFactor does not support predict decisionfunction and scoresamples methods by default but only a fitpredict method as this estimator was originally meant to be applied for outlier detection The scores of abnormality of the training samples are accessible through the negativeoutlierfactor attribute
If you really want to use neighborsLocalOutlierFactor for novelty detection ie predict labels or compute the score of abnormality of new unseen data you can instantiate the estimator with the novelty parameter set to True before fitting the estimator In this case fitpredict is not available

Warning Novelty detection with Local Outlier Factor

When novelty is set to True be aware that you must only use predict decisionfunction and scoresamples on new unseen data and not on the training samples as this would lead to wrong results The scores of abnormality of the training samples are always accessible through the negativeoutlierfactor attribute

The behavior of neighborsLocalOutlierFactor is summarized in the following table

| Method | Outlier detection | Novelty detection |
|------------------|---------------------------|----------------------|
| fitpredict | OK | Not available |
| predict | Not available | Use only on new data |
| decisionfunction | Not available | Use only on new data |
| scoresamples | Use negativeoutlierfactor | Use only on new data |

Overview of outlier detection methods

A comparison of the outlier detection algorithms in scikitlearn Local Outlier Factor LOF does not show a decision boundary in black as it has no predict method to be applied on new data when it is used for outlier detection ensembleIsolationForest and neighborsLocalOutlierFactor perform reasonably well on the data sets considered here The svmOneClassSVM is known to be sensitive to outliers and thus does not perform very well for outlier detection Finally covarianceEllipticEnvelope assumes the data is Gaussian and learns an ellipse For more details on the different estimators refer to the example Comparing anomaly detection algorithms for outlier detection on toy datasets and the sections hereunder

Examples

- See Comparing anomaly detection algorithms for outlier detection on toy datasets for a comparison of the svmOneClassSVM the ensembleIsolationForest the neighborsLocalOutlierFactor and covarianceEllipticEnvelope

Novelty Detection

Consider a data set of n observations from the same distribution described by d features Consider now that we add one more observation to that data set Is the new observation so different from the others that we can doubt it is regular ie does it come from the same distribution Or on the contrary is it so similar to the other that we cannot distinguish it from the original observations This is the question addressed by the novelty detection tools and methods In general it is about to learn a rough close frontier delimiting the contour of the initial observations distribution plotted in embedding d -dimensional space Then if further observations lay within the frontier delimited subspace

scikitlearn user guide Release 0213

they are considered as coming from the same population than the initial observations Otherwise if they lay outside the frontier we can say that they are abnormal with a given confidence in our assessment

The OneClass SVM (Support Vector Machine) has been introduced by Schölkopf et al for that purpose and implemented in the Support Vector Machines module in the svmOneClassSVM object It requires the choice of a kernel and a scalar parameter to define a frontier The RBF (Radial Basis Function) kernel is usually chosen although there exists no exact formula or algorithm to set its bandwidth parameter This is the default in the scikitlearn implementation The γ parameter also known as the margin of the OneClass SVM (Support Vector Machine) corresponds to the probability of finding a new but regular observation outside the frontier

Examples

- See Oneclass SVM (Support Vector Machine) with nonlinear kernel RBF (Radial Basis Function) for visualizing the frontier learned around some data
- svmOneClassSVM object
- Species distribution modeling

Outlier Detection

Outlier detection is similar to novelty detection in the sense that the goal is to separate a core of regular observations from some polluting ones called outliers Yet in the case of outlier detection we don't have a clean data set representing the population of regular observations that can be used to train any tool

scikitlearn user guide Release 0213

Fitting an elliptic envelope

One common way of performing outlier detection is to assume that the regular data come from a known distribution eg data are Gaussian distributed From this assumption we generally try to define the “shape” of the data and can define outlying observations as observations which stand far enough from the fit shape The scikitlearn provides an object covarianceEllipticEnvelope that fits a robust covariance estimate to the data and thus fits an ellipse to the central data points ignoring points outside the central mode For instance assuming that the inlier data are Gaussian distributed it will estimate the inlier location and covariance in a robust way ie without being influenced by outliers The Mahalanobis distances obtained from this estimate is used to derive a measure of outlyingness This strategy is illustrated below

Examples

- See Robust covariance estimation and Mahalanobis distances relevance for an illustration of the difference between using a standard covarianceEmpiricalCovariance or a robust estimate covarianceMinCovDet of location and covariance to assess the degree of outlyingness of an observation

- 422 Chapter 3 User Guide

Isolation Forest

One efficient way of performing outlier detection in highdimensional datasets is to use random forests The ensembleIsolationForest ‘isolates’ observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature Since recursive partitioning can be represented by a tree structure the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node This path length averaged over a forest of such random trees is a measure of normality and our decision function Random partitioning produces noticeably shorter paths for anomalies Hence when a forest of random trees collectively produce shorter path lengths for particular samples they are highly likely to be anomalies The implementation of ensembleIsolationForest is based on an ensemble of tree ExtraTreeRegressor Following Isolation Forest original paper the maximum depth of each tree is set to $\lceil \log_2 n \rceil$ where n is the number of samples used to build the tree see Liu et al 2008 for more details This algorithm is illustrated below The ensembleIsolationForest supportswarmstartTrue which allows you to add more trees to an already fitted model

```
from sklearnensemble import IsolationForest
import numpy as np
X = np.array([1, 2, 1, 3, 2, 0, 0, 20, 50, 3, 5])
clf = IsolationForest(n_estimators=10, warmstart=True)
clf.fit(X) # fit 10 trees
clf.set_params(n_estimators=20) # add 10 more trees
clf.fit(X) # fit the added trees
```

Examples

Local Outlier Factor

Another efficient way to perform outlier detection on moderately high dimensional datasets is to use the Local Outlier Factor LOF algorithm

TheneighborsLocalOutlierFactor LOF algorithm computes a score called local outlier factor reflecting the degree of abnormality of the observations. It measures the local density deviation of a given data point with respect to its neighbors. The idea is to detect the samples that have a substantially lower density than their neighbors. In practice, the local density is obtained from the k nearest neighbors. The LOF score of an observation is equal to the ratio of the average local density of its k nearest neighbors and its own local density. A normal instance is expected to have a local density similar to that of its neighbors, while abnormal data are expected to have much smaller local density.

The number k of neighbors considered (alias parameter nneighbors) is typically chosen 1 greater than the minimum number of objects a cluster has to contain so that other objects can be local outliers relative to this cluster and 2 smaller than the maximum number of close-by objects that can potentially be local outliers. In practice, such information is generally not available, and taking nneighbors=20 appears to work well in general. When the proportion of outliers is high (i.e. greater than 10%) as in the example below, nneighbors should be greater (nneighbors=35 in the example below).

The strength of the LOF algorithm is that it takes both local and global properties of datasets into consideration; it can perform well even in datasets where abnormal samples have different underlying densities. The question is not how isolated the sample is, but how isolated it is with respect to the surrounding neighborhood.

When applying LOF for outlier detection, there are no predict, decisionfunction, and scoresamples methods, but only a fitpredict method. The scores of abnormality of the training samples are accessible through the negativeoutlierfactor attribute. Note that predict, decisionfunction, and scoresamples can be used on new, unseen data when LOF is applied for novelty detection (i.e. when the novelty parameter is set to True). See Novelty detection with Local Outlier Factor.

This strategy is illustrated below.

Examples

- See Outlier detection with Local Outlier Factor LOF for an illustration of the use of neighbors

LocalOutlierFactor

- See Comparing anomaly detection algorithms for outlier detection on toy datasets for a comparison with other anomaly detection methods

Novelty detection with Local Outlier Factor

To use neighborsLocalOutlierFactor for novelty detection ie predict labels or compute the score of abnormality of new unseen data you need to instantiate the estimator with the novelty parameter set to True before fitting the estimator

lof = LocalOutlierFactornovelty=True

lof.fit(Xtrain)

Note that fit_predict is not available in this case

Warning Novelty detection with Local Outlier Factor'

When novelty is set to True be aware that you must only use predict decision function

and score samples on new unseen data and not on the training samples as this would lead to

wrong results The scores of abnormality of the training samples are always accessible through the

negative_outlier_factor_ attribute

Novelty detection with Local Outlier Factor is illustrated below

328 Density Estimation

Density estimation walks the line between unsupervised learning feature engineering and data modeling Some of the most popular and useful density estimation techniques are mixture models such as Gaussian Mixtures `sklearn.mixture.GaussianMixture` and neighborbased approaches such as the kernel density estimate `sklearn.neighbors.KernelDensity` Gaussian Mixtures are discussed more fully in the context of clustering because the technique is also useful as an unsupervised clustering scheme

Density estimation is a very simple concept and most people are already familiar with one common density estimation technique the histogram

Density Estimation Histograms

A histogram is a simple visualization of data where bins are defined and the number of data points within each bin is tallied An example of a histogram can be seen in the upperleft panel of the following figure

scikitlearn user guide Release 0213

A major problem with histograms however is that the choice of binning can have a disproportionate effect on the resulting visualization Consider the upperright panel of the above figure It shows a histogram over the same data with the bins shifted right The results of the two visualizations look entirely different and might lead to different interpretations of the data

Intuitively one can also think of a histogram as a stack of blocks one block per point By stacking the blocks in the appropriate grid space we recover the histogram But what if instead of stacking the blocks on a regular grid we center each block on the point it represents and sum the total height at each location This idea leads to the lowerleft visualization It is perhaps not as clean as a histogram but the fact that the data drive the block locations mean that it is a much better representation of the underlying data

This visualization is an example of a kernel density estimation in this case with a tophat kernel ie a square block at each point We can recover a smoother distribution by using a smoother kernel The bottomright plot shows a Gaussian kernel density estimate in which each point contributes a Gaussian curve to the total The result is a smooth density estimate which is derived from the data and functions as a powerful nonparametric model of the distribution of points

Kernel Density Estimation

Kernel density estimation in scikitlearn is implemented in the sklearnneighborsKernelDensity estimator which uses the Ball Tree or KD Tree for efficient queries see Nearest Neighbors for a discussion of these Though the above example uses a 1D data set for simplicity kernel density estimation can be performed in any number of dimensions though in practice the curse of dimensionality causes its performance to degrade in high dimensions In the following figure 100 points are drawn from a bimodal distribution and the kernel density estimates are shown for three choices of kernels

scikitlearn user guide Release 0213

It's clear how the kernel shape affects the smoothness of the resulting distribution The scikitlearn kernel density estimator can be used as follows

```
from sklearn.neighbors.kde import KernelDensity
import numpy as np
X = np.array([1, 2, 1, 3, 2, 1, 1, 2, 1, 3, 2])
kde = KernelDensity(kernel='gaussian', bandwidth=0.2).fit(X)
kde.score_samples(X)
array([0.41075698, 0.41075698, 0.41076071, 0.41075698, 0.41075698,
       0.41076071])
```

Here we have used kernelgaussian as seen above Mathematically a kernel is a positive function $K(x, x')$ which is controlled by the bandwidth parameter h Given this kernel form the density estimate at a point x within a group of points x_1, \dots, x_n is given by

$$\hat{p}(x) = \frac{1}{n} \sum_{i=1}^n K(x, x_i) / h$$

The bandwidth here acts as a smoothing parameter controlling the tradeoff between bias and variance in the result A large bandwidth leads to a very smooth ie highbias density distribution A small bandwidth leads to an unsmooth ie highvariance density distribution

sklearn.neighbors.KernelDensity implements several common kernel forms which are shown in the following figure

scikitlearn user guide Release 0213

The form of these kernels is as follows

- Gaussian kernel kernel gaussian

$$K(x,y)=\exp\left(-\frac{\|x-y\|^2}{2h^2}\right)$$

- Tophat kernel kernel tophat

$$K(x,y)=\frac{1}{h}\exp\left(-\frac{\|x-y\|}{h}\right)$$

- Epanechnikov kernel kernel epanechnikov

$$K(x,y)=\frac{3}{4h}\left(1-\frac{\|x-y\|^2}{h^2}\right)$$

- Exponential kernel kernel exponential

$$K(x,y)=\exp\left(-\frac{\|x-y\|}{h}\right)$$

- Linear kernel kernel linear

$$K(x,y)=\frac{1}{h}\left(1-\frac{\|x-y\|}{h}\right)$$

- Cosine kernel kernel cosine

$$K(x,y)=\cos\left(\frac{\|x-y\|}{h}\right)$$

$$K(x,y)=\frac{1}{2h}\exp\left(-\frac{\|x-y\|}{h}\right)$$

The kernel density estimator can be used with any of the valid distance metrics see sklearnneighbors

DistanceMetric for a list of available metrics though the results are properly normalized only for the Euclidean

metric One particularly useful metric is the Haversine distance which measures the angular distance between points

on a sphere Here is an example of using a kernel density estimate for a visualization of geospatial data in this case

the distribution of observations of two different species on the South American continent

One other useful application of kernel density estimation is to learn a nonparametric generative model of a dataset in order to efficiently draw new samples from this generative model Here is an example of using this process to create a new set of handwritten digits using a Gaussian kernel learned on a PCA (Principal Component Analysis) projection of the data The “new” data consists of linear combinations of the input data with weights probabilistically drawn given the KDE model

scikitlearn user guide Release 0213

Examples

- Simple 1D Kernel Density Estimation computation of simple kernel density estimates in one dimension
- Kernel Density Estimation an example of using Kernel Density estimation to learn a generative model of the handwritten digits data and drawing new samples from this model
- Kernel Density Estimate of Species Distributions an example of Kernel Density estimation using the Haver sine distance metric to visualize geospatial data

329 Neural network models unsupervised

Restricted Boltzmann machines

Restricted Boltzmann machines RBM are unsupervised nonlinear feature learners based on a probabilistic model

The features extracted by an RBM or a hierarchy of RBMs often give good results when fed into a linear classifier

such as a linear SVM (Support Vector Machine) or a perceptron

The model makes assumptions regarding the distribution of inputs At the moment scikitlearn only provides

BernoulliRBM which assumes the inputs are either binary values or values between 0 and 1 each encoding the

probability that the specific feature would be turned on

The RBM tries to maximize the likelihood of the data using a particular graphical model The parameter learning

algorithm used Stochastic Maximum Likelihood prevents the representations from straying far from the input data

which makes them capture interesting regularities but makes the model less useful for small datasets and usually not

useful for density estimation

The method gained popularity for initializing deep neural networks with the weights of independent RBMs This

method is known as unsupervised pretraining

Examples

- Restricted Boltzmann Machine features for digit classification

Graphical model and parametrization

The graphical model of an RBM is a fullyconnected bipartite graph

32 Unsupervised learning 431

The nodes are random variables whose states depend on the state of the other nodes they are connected to The model is therefore parameterized by the weights of the connections as well as one intercept bias term for each visible and hidden unit omitted from the image for simplicity

The energy function measures the quality of a joint assignment

$$E(v,h) = -\sum_{i,j} w_{ij} v_i h_j - \sum_i b_i v_i - \sum_j c_j h_j$$

In the formula above b and c are the intercept vectors for the visible and hidden layers respectively The joint

probability of the model is defined in terms of the energy

$$E(\mathbf{v}, \mathbf{h}) = -\sum_i v_i \sum_j w_{ij} h_j$$

The word restricted refers to the bipartite structure of the model which prohibits direct interaction between hidden units or between visible units This means that the following conditional independencies are assumed

$$h_i \perp h_j \mid \mathbf{v}$$
$$v_i \perp v_j \mid \mathbf{h}$$

The bipartite structure allows for the use of efficient block Gibbs sampling for inference

Bernoulli Restricted Boltzmann machines

In the BernoulliRBM all units are binary stochastic units This means that the input data should either be binary or realvalued between 0 and 1 signifying the probability that the visible unit would turn on or off This is a good model for character recognition where the interest is on which pixels are active and which aren't For images of natural scenes it no longer fits because of background depth and the tendency of neighbouring pixels to take the same values The conditional probability distribution of each unit is given by the logistic sigmoid activation function of the input it receives

$$p(h_i = 1 | \mathbf{v}) = \sigma(\sum_j w_{ij} v_j)$$
$$p(v_i = 1 | \mathbf{h}) = \sigma(\sum_j w_{ji} h_j)$$

where σ is the logistic sigmoid function

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

Stochastic Maximum Likelihood learning

The training algorithm implemented in BernoulliRBM is known as Stochastic Maximum Likelihood SML or Persistent Contrastive Divergence PCD Optimizing maximum likelihood directly is infeasible because of the form of the data likelihood

$$\log p(\mathbf{v}, \mathbf{h}) = \log \sum_{\mathbf{h}} p(\mathbf{h} | \mathbf{v}) p(\mathbf{v} | \mathbf{h})$$

For simplicity the equation above is written for a single training example The gradient with respect to the weights is formed of two terms corresponding to the ones above They are usually known as the positive gradient and the negative gradient because of their respective signs In this implementation the gradients are estimated over minibatches of samples

In maximizing the loglikelihood the positive gradient makes the model prefer hidden states that are compatible with the observed training data Because of the bipartite structure of RBMs it can be computed efficiently The negative gradient however is intractable Its goal is to lower the energy of joint states that the model prefers therefore making it stay true to the data It can be approximated by Markov chain Monte Carlo using block Gibbs sampling by iteratively sampling each of \mathbf{v} and \mathbf{h} given the other until the chain mixes Samples generated in this way are sometimes referred as fantasy particles This is inefficient and it is difficult to determine whether the Markov chain mixes

The Contrastive Divergence method suggests to stop the chain after a small number of iterations k usually even 1

This method is fast and has low variance but the samples are far from the model distribution

scikitlearn user guide Release 0213

Persistent Contrastive Divergence addresses this. Instead of starting a new chain each time the gradient is needed and performing only one Gibbs sampling step in PCD we keep a number of chains (fantasy particles) that are updated \square Gibbs steps after each weight update. This allows the particles to explore the space more thoroughly.

33 Model selection and evaluation

331 Crossvalidation evaluating estimator performance

Learning the parameters of a prediction function and testing it on the same data is a methodological mistake: a model that would just repeat the labels of the samples that it has just seen would have a perfect score but would fail to predict anything useful on yet-unseen data. This situation is called overfitting. To avoid it, it is common practice when performing a supervised machine learning experiment to hold out part of the available data as a test set. X_{test} y_{test} . Note that the word “experiment” is not intended to denote academic use only because even in commercial settings machine learning usually starts out experimentally. Here is a flowchart of typical cross validation workflow in model training. The best parameters can be determined by grid search techniques.

In scikitlearn a random split into training and test sets can be quickly computed with the `train_test_split` helper function. Let’s load the iris data set to fit a linear support vector machine on it.

```
import numpy as np
from sklearn.model_selection import train_test_split
from sklearn import datasets
from sklearn import svm
iris = datasets.load_iris()
iris_data_shape = iris.target_shape
150 4 150
```

We can now quickly sample a training set while holding out 40% of the data for testing, evaluating our classifier.

```
scikitlearn user guide Release 0213
Xtrain Xtest ytrain ytest traintestsplit
irisdata iristarget testsize04 randomstate0
Xtrainshape ytrainshape
90 4 90
Xtestshape ytestshape
60 4 60
clf svmSVCKernellinear C1fitXtrain ytrain
clfscoreXtest ytest
096
```

When evaluating different settings “hyperparameters” for estimators such as the Csetting that must be manually set for an SVM (Support Vector Machine) there is still a risk of overfitting on the test set because the parameters can be tweaked until the estimator performs optimally This way knowledge about the test set can “leak” into the model and evaluation metrics no longer report on generalization performance To solve this problem yet another part of the dataset can be held out as a so called “validation set” training proceeds on the training set after which evaluation is done on the validation set and when the experiment seems to be successful final evaluation can be done on the test set However by partitioning the available data into three sets we drastically reduce the number of samples which can be used for learning the model and the results can depend on a particular random choice for the pair of train validation sets

A solution to this problem is a procedure called crossvalidation CV (Cross-Validation) for short A test set should still be held out for final evaluation but the validation set is no longer needed when doing CV (Cross-Validation) In the basic approach called kfold CV (Cross-Validation) training set is split into ksmaller sets other approaches are described below but generally follow the same principles

The following procedure is followed for each of the k“folds”

- A model is trained using $\frac{n-1}{k}$ of the folds as training data
- the resulting model is validated on the remaining part of the data ie it is used as a test set to compute a performance measure such as accuracy

The performance measure reported by kfold crossvalidation is then the average of the values computed in the loop

This approach can be computationally expensive but does not waste too much data as is the case when fixing an arbitrary validation set which is a major advantage in problems such as inverse inference where the number of samples is very small

scikitlearn user guide Release 0213

Computing crossvalidated metrics

The simplest way to use crossvalidation is to call the crossvalscore helper function on the estimator and the dataset

The following example demonstrates how to estimate the accuracy of a linear kernel support vector machine on the iris dataset by splitting the data fitting a model and computing the score 5 consecutive times with different splits each time

```
from sklearn.model_selection import crossvalscore
clf = svm.SVC(kernel='linear', C=1)
scores = crossvalscore(clf, iris.data, iris.target, cv=5)
scores
array([0.96, 1.   , 0.96, 0.96, 1.   ])
```

The mean score and the 95 confidence interval of the score estimate are hence given by

```
print(Accuracy(0.2f, 0.2f), scores.mean(), scores.std() * 2)
Accuracy: 0.98 ± 0.03
```

By default the score computed at each CV (Cross-Validation) iteration is the score method of the estimator. It is possible to change this by using the scoring parameter

```
from sklearn import metrics
scores = crossvalscore(
    clf, iris.data, iris.target, cv=5, scoring='f1_macro')
scores
array([0.96, 1.   , 0.96, 0.96, 1.   ])
```

See The scoring parameter defining model evaluation rules for details. In the case of the Iris dataset the samples are balanced across target classes hence the accuracy and the F1score are almost equal

When the cv argument is an integer crossvalscore uses the KFold or StratifiedKFold strategies by default the latter being used if the estimator derives from ClassifierMixin

It is also possible to use other cross validation strategies by passing a cross validation iterator instead for instance

```
from sklearn.model_selection import ShuffleSplit
n_samples = iris.data.shape[0]
cv = ShuffleSplit(n_splits=5, test_size=0.3, random_state=0)
crossvalscore(clf, iris.data, iris.target, cv=cv)
array([0.977, 0.977, 1.   , 0.955, 1.   ])
```

Another option is to use an iterable yielding train test splits as arrays of indices for example

```
def customcv2folds(X):
    n = X.shape[0]
    i = 1
    while i < 2:
        idx, npar = generate(i, 1, 2, n, i, 2, dtype=int)
        yield idx, idx
        i = 1
```

```
customcv = customcv2folds(iris.data)
crossvalscore(clf, iris.data, iris.target, cv=customcv)
array([1.   , 0.973])
```

scikitlearn user guide Release 0213

Data transformation with held out data

Just as it is important to test a predictor on data heldout from training preprocessing such as standardization feature selection etc and similar data transformations similarly should be learnt from a training set and applied to heldout data for prediction

```
from sklearn import preprocessing
Xtrain Xtest ytrain ytest traintestsplit
irisdata iristarget testsize04 randomstate0
scaler preprocessingStandardScalerfitXtrain
Xtraintransformed scalertransformXtrain
clf svmSVCC1fitXtraintransformed ytrain
Xtesttransformed scalertransformXtest
clfscoreXtesttransformed ytest
09333
```

APipeline makes it easier to compose estimators providing this behavior under crossvalidation

```
from sklearnpipeline import makepipeline
clf makepipelinepreprocessingStandardScaler svmSVCC1
crossvalscoreclf irisdata iristarget cvcv
```

The crossvalidate function and multiple metric evaluation

Thecrossvalidate function differs from crossvalscore in two ways

- It allows specifying multiple metrics for evaluation
- It returns a dict containing fittimes scoretimes and optionally training scores as well as fitted estimators in addition to the test score

For single metric evaluation where the scoring parameter is a string callable or None the keys will be

testscore fittime scoretime

And for multiple metric evaluation the return value is a dict with the following keys

testscorer1name testscorer2name testscorer fittime
scoretime

returntrainscore is set toFalse by default to save computation time To evaluate the scores on the training set as well you need to be set to True

You may also retain the estimator fitted on each training set by setting returnestimatorTrue

The multiple metrics can be specified either as a list tuple or set of predefined scorer names

```
from sklearnmodelselection import crossvalidate
from sklearnmetrics import recallscore
scoring precisionmacro recallmacro
clf svmSVCKernellinear C1 randomstate0
scores crossvaldateclf irisdata iristarget scoringscoring
cv5
sortedscoreskeys
fittime scoretime testprecisionmacro testrecallmacro
scorestestrecallmacro
array096 1 096 096 1
33 Model selection and evaluation 437
```

scikitlearn user guide Release 0213

Or as a dict mapping scorer name to a predefined or custom scoring function

from sklearn.metrics.scorer import makescorer

scoring {'precisionmacro', 'precisionmacro'}

Obtaining predictions by crossvalidation

The function crossvalpredict has a similar interface to crossvalscore but returns for each element

in the input the prediction that was obtained for that element when it was in the test set Only crossvalidation

strategies that assign all elements to a test set exactly once can be used otherwise an exception is raised

Warning Note on inappropriate usage of crossvalpredict

The result of crossvalpredict may be different from those obtained using crossvalscore as the

elements are grouped in different ways The function crossvalscore takes an average over crossvalidation

folds whereas crossvalpredict simply returns the labels or probabilities from several distinct models

undistinguished Thus crossvalpredict is not an appropriate measure of generalisation error

The function crossvalpredict is appropriate for

- Visualization of predictions obtained from different models
- Model blending When predictions of one supervised estimator are used to train another estimator in ensemble methods

The available cross validation iterators are introduced in the following section

Examples

- Receiver Operating Characteristic ROC with cross validation
 - Recursive feature elimination with crossvalidation
 - Parameter estimation using grid search with crossvalidation
 - Sample pipeline for text feature extraction and evaluation
 - Plotting CrossValidated Predictions
 - Nested versus nonnested crossvalidation
- 438 Chapter 3 User Guide

scikitlearn user guide Release 0213

Cross validation iterators

The following sections list utilities to generate indices that can be used to generate dataset splits according to different cross validation strategies

Crossvalidation iterators for iid data

Assuming that some data is Independent and Identically Distributed iid is making the assumption that all samples stem from the same generative process and that the generative process is assumed to have no memory of past generated samples

The following crossvalidators can be used in such cases

NOTE

While iid data is a common assumption in machine learning theory it rarely holds in practice If one knows that the samples have been generated using a timedependent process it’s safer to use a timeseries aware crossvalidation scheme Similarly if we know that the generative process has a group structure samples from collected from different subjects experiments measurement devices it safer to use groupwise crossvalidation

Kfold

KFold divides all the samples in k groups of samples called folds if $k=1$ this is equivalent to the Leave One Out strategy of equal sizes if possible The prediction function is learned using $k-1$ folds and the fold left out is used for test

Example of 2fold crossvalidation on a dataset with 4 samples

```
import numpy as np
from sklearn.modelselection import KFold
X = a b c d
kf = KFold(n_splits=2)
for train test in kf.split(X):
    print(s, 'train test')
2 3 0 1
0 1 2 3
```

Here is a visualization of the crossvalidation behavior Note that KFold is not affected by classes or groups

scikitlearn user guide Release 0213

Each fold is constituted by two arrays the first one is related to the training set and the second one to the test set
Thus one can create the trainingtest sets using numpy indexing

```
X nparray0 0 1 1 1 1 2 2
y nparray0 1 0 1
Xtrain Xtest ytrain ytest  Xtrain Xtest ytrain ytest
```

Repeated KFold

RepeatedKFold repeats KFold n times It can be used when one requires to run KFold n times producing
different splits in each repetition

Example of 2fold KFold repeated 2 times

```
import numpy as np
from sklearnmodelselection import RepeatedKFold
X nparray1 2 3 4 1 2 3 4
randomstate 12883823
rkf RepeatedKFoldnplits2 nrepeats2 randomstaterandomstate
for train test inrkfsplitX
prints s train test
```

```
2 3 0 1
0 1 2 3
0 2 1 3
1 3 0 2
```

SimilarlyRepeatedStratifiedKFold repeats Stratified KFold n times with different randomization in each
repetition

Leave One Out LOO

LeaveOneOut or LOO is a simple crossvalidation Each learning set is created by taking all the samples except
one the test set being the sample left out Thus for n samples we have n different training sets and n different tests
set This crossvalidation procedure does not waste much data as only one sample is removed from the training set

```
from sklearnmodelselection import LeaveOneOut
X 1 2 3 4
loo LeaveOneOut
for train test inloosplitX
prints s train test
```

```
1 2 3 0
0 2 3 1
0 1 3 2
0 1 2 3
```

Potential users of LOO for model selection should weigh a few known caveats When compared with nfold cross
validation one builds nmodels from n samples instead of nmodels where n n Moreover each is trained on n-1
samples rather than n-1 In both ways assuming n is not too large and n n LOO is more computationally
expensive than nfold cross validation

In terms of accuracy LOO often results in high variance as an estimator for the test error Intuitively since n-1of
the n samples are used to build each model models constructed from folds are virtually identical to each other and to
the model built from the entire training set

scikitlearn user guide Release 0213

However if the learning curve is steep for the training size in question then 5 or 10 fold cross validation can overestimate the generalization error

As a general rule most authors and empirical evidence suggest that 5 or 10 fold cross validation should be preferred to LOO

Leave P Out LPO

LeavePOut is very similar to LeaveOneOut as it creates all the possible trainingtest sets by removing $\frac{1}{n}$ samples from the complete set For $\frac{1}{n}$ samples this produces $\frac{1}{n}$

$\frac{1}{n}$ traintest pairs Unlike LeaveOneOut and KFold the test sets will overlap for $\frac{1}{n}$

Example of Leave2Out on a dataset with 4 samples

```
from sklearn.model_selection import LeavePOut
X = np.ones(4)
```

```
lpo = LeavePOut(2)
for train, test in lpo.split(X):
    print(s, train, test)
2 3 0 1
1 3 0 2
1 2 0 3
0 3 1 2
0 2 1 3
0 1 2 3
```

Random permutations crossvalidation aka Shuffle Split

ShuffleSplit

The ShuffleSplit iterator will generate a user defined number of independent train test dataset splits Samples are first shuffled and then split into a pair of train and test sets

It is possible to control the randomness for reproducibility of the results by explicitly seeding the randomstate pseudo random number generator

Here is a usage example

33 Model selection and evaluation 441

```
scikitlearn user guide Release 0213
from sklearn.model_selection import ShuffleSplit
X np.arange(10)
ss ShuffleSplit(n_splits=5, test_size=0.25,
random_state=0)
for train_index, test_index in ss.split(X):
    print(train_index, test_index)
9 1 6 7 3 0 5 2 8 4
2 9 8 0 6 7 4 3 5 1
4 5 1 0 6 9 7 2 3 8
2 7 5 8 0 3 4 6 1 9
4 1 0 6 8 9 3 5 2 7
```

Here is a visualization of the crossvalidation behavior Note that ShuffleSplit is not affected by classes or groups

ShuffleSplit is thus a good alternative to KFold cross validation that allows a finer control on the number of iterations and the proportion of samples on each side of the train test split

Crossvalidation iterators with stratification based on class labels

Some classification problems can exhibit a large imbalance in the distribution of the target classes for instance there could be several times more negative samples than positive samples In such cases it is recommended to use stratified sampling as implemented in StratifiedKFold and StratifiedShuffleSplit to ensure that relative class frequencies is approximately preserved in each train and validation fold

Stratified kfold

StratifiedKFold is a variation of kfold which returns stratified folds each set contains approximately the same percentage of samples of each target class as the complete set

Example of stratified 3fold crossvalidation on a dataset with 10 samples from two slightly unbalanced classes

```
from sklearn.model_selection import StratifiedKFold
X np.ones(10)
y 0 0 0 0 1 1 1 1 1 1
skf StratifiedKFold(n_splits=3)
for train, test, index in skf.split(X, y):
    # ...
442 Chapter 3 User Guide
```

scikitlearn user guide Release 0213

prints s train test

2 3 6 7 8 9 0 1 4 5

0 1 3 4 5 8 9 2 6 7

0 1 2 4 5 6 7 3 8 9

Here is a visualization of the crossvalidation behavior

RepeatedStratifiedKFold can be used to repeat Stratified KFold n times with different randomization in each repetition

Stratified Shuffle Split

StratifiedShuffleSplit is a variation of ShuffleSplit which returns stratified splits iewhich creates splits by preserving the same percentage for each target class as in the complete set

Here is a visualization of the crossvalidation behavior

Crossvalidation iterators for grouped data

The iid assumption is broken if the underlying generative process yield groups of dependent samples

33 Model selection and evaluation 443

scikitlearn user guide Release 0213

Such a grouping of data is domain specific An example would be when there is medical data collected from multiple patients with multiple samples taken from each patient And such data is likely to be dependent on the individual group In our example the patient id for each sample will be its group identifier

In this case we would like to know if a model trained on a particular set of groups generalizes well to the unseen groups To measure this we need to ensure that all the samples in the validation fold come from groups that are not represented at all in the paired training fold

The following crossvalidation splitters can be used to do that The grouping identifier for the samples is specified via thegroups parameter

Group kfold

GroupKFold is a variation of kfold which ensures that the same group is not represented in both testing and training sets For example if the data is obtained from different subjects with several samples persubject and if the model is flexible enough to learn from highly person specific features it could fail to generalize to new subjects GroupKFold makes it possible to detect this kind of overfitting situations

Imagine you have three subjects each with an associated number from 1 to 3

from sklearnmodelselection import GroupKFold

X 01 02 22 24 23 455 58 88 9 10

y a b b b c c c d d d

groups 1 1 1 2 2 2 3 3 3 3

gkf GroupKFoldnplits3

for train test ingkfsplitX y groupsgroups

prints s train test

0 1 2 3 4 5 6 7 8 9

0 1 2 6 7 8 9 3 4 5

3 4 5 6 7 8 9 0 1 2

Each subject is in a different testing fold and the same subject is never in both testing and training Notice that the folds do not have exactly the same size due to the imbalance in the data

Here is a visualization of the crossvalidation behavior

444 Chapter 3 User Guide

Leave One Group Out

LeaveOneGroupOut is a crossvalidation scheme which holds out the samples according to a thirdparty provided array of integer groups This group information can be used to encode arbitrary domain specific predefined cross validation folds

Each training set is thus constituted by all the samples except the ones related to a specific group

For example in the cases of multiple experiments LeaveOneGroupOut can be used to create a crossvalidation based on the different experiments we create a training set using the samples of all the experiments except one

from sklearnmodelselection import LeaveOneGroupOut

X 1 5 10 50 60 70 80

y 0 1 1 2 2 2 2

groups 1 1 2 2 3 3 3

lgo = LeaveOneGroupOut

for train test in lgo.split(X, y, groups):

print('train: %s test: %s' % (train, test))

2 3 4 5 6 0 1

0 1 4 5 6 2 3

0 1 2 3 4 5 6

Another common application is to use time information for instance the groups could be the year of collection of the samples and thus allow for crossvalidation against timebased splits

Leave P Groups Out

LeavePGroupsOut is similar as LeaveOneGroupOut but removes samples related to p groups for each train

ingtest set

Example of Leave2Group Out

from sklearnmodelselection import LeavePGroupsOut

X = np.arange(6)

y = [1, 1, 1, 2, 2, 2]

groups = [1, 1, 2, 2, 3, 3]

lpgo = LeavePGroupsOut(n_groups=2)

for train test in lpgo.split(X, y, groups):

print('train: %s test: %s' % (train, test))

4 5 0 1 2 3

2 3 0 1 4 5

0 1 2 3 4 5

Group Shuffle Split

TheGroupShuffleSplit iterator behaves as a combination of ShuffleSplit and LeavePGroupsOut and generates a sequence of randomized partitions in which a subset of groups are held out for each split

Here is a usage example

from sklearnmodelselection import GroupShuffleSplit

X = [0, 1, 2, 2, 2, 4, 2, 3, 4, 5, 5, 8, 0, 0, 0, 1]

y = ['a', 'b', 'b', 'b', 'c', 'c', 'c', 'a']

```
scikitlearn user guide Release 0213
groups 1 1 2 2 3 3 4 4
gss GroupShuffleSplitn_splits4 testsize05 randomstate0
for train test ingsssplitX y groupsgroups
prints s train test
```

```
0 1 2 3 4 5 6 7
2 3 6 7 0 1 4 5
2 3 4 5 0 1 6 7
4 5 6 7 0 1 2 3
```

Here is a visualization of the crossvalidation behavior

This class is useful when the behavior of LeavePGroupsOut is desired but the number of groups is large enough that generating all possible partitions with $\frac{1}{p}$ groups withheld would be prohibitively expensive In such a scenario GroupShuffleSplit provides a random sample with replacement of the train test splits generated by LeavePGroupsOut

Predefined FoldSplits ValidationSets

For some datasets a predefined split of the data into training and validation fold or into several crossvalidation folds already exists Using PredefinedSplit it is possible to use these folds eg when searching for hyperparameters

For example when using a validation set set the testfold to 0 for all samples that are part of the validation set and to 1 for all other samples

Cross validation of time series data

Time series data is characterised by the correlation between observations that are near in time autocorrelation However classical crossvalidation techniques such as KFold and ShuffleSplit assume the samples are independent and identically distributed and would result in unreasonable correlation between training and testing instances yielding poor estimates of generalisation error on time series data Therefore it is very important to evaluate our model for time series data on the “future” observations least like those that are used to train the model To achieve this one solution is provided by TimeSeriesSplit

446 Chapter 3 User Guide

scikitlearn user guide Release 0213

Time Series Split

TimeSeriesSplit is a variation of kfold which returns first k folds as train set and the $k + 1$ th fold as test set
Note that unlike standard crossvalidation methods successive training sets are supersets of those that come before them Also it adds all surplus data to the first training partition which is always used to train the model
This class can be used to crossvalidate time series data samples that are observed at fixed time intervals

Example of 3split time series crossvalidation on a dataset with 6 samples

```
from sklearn.model_selection import TimeSeriesSplit
```

```
X = np.array([1, 2, 3, 4, 1, 2, 3, 4, 1, 2, 3, 4])
```

```
y = np.array([1, 2, 3, 4, 5, 6])
```

```
tscv = TimeSeriesSplit(n_splits=3)
```

```
print(tscv
```

```
TimeSeriesSplit(max_train_size=None, n_splits=3)
```

```
for train, test in tscv.split(X):
```

```
    print('train:', train, 'test:', test)
```

```
0 1 2 3
```

```
0 1 2 3 4
```

```
0 1 2 3 4 5
```

Here is a visualization of the crossvalidation behavior

A note on shuffling

If the data ordering is not arbitrary eg samples with the same class label are contiguous shuffling it first may be essential to get a meaningful cross validation result However the opposite may be true if the samples are not independently and identically distributed For example if samples correspond to news articles and are ordered by their time of publication then shuffling the data will likely lead to a model that is overfit and an inflated validation score it will be tested on samples that are artificially similar close in time to training samples

Some cross validation iterators such as KFold have an inbuilt option to shuffle the data indices before splitting them

Note that

- This consumes less memory than shuffling the data directly
- By default no shuffling occurs including for the stratified K fold cross validation performed by specifying cv=SomeInteger to cross_val_score grid search etc Keep in mind that train_test_split

still returns a random split

scikitlearn user guide Release 0213

- Therandomstate parameter defaults to None meaning that the shuffling will be different every time KFold shuffleTrue is iterated However GridSearchCV will use the same shuffling for each set of parameters validated by a single call to its fit method
- To get identical results for each split set randomstate to an integer

Cross validation and model selection

Cross validation iterators can also be used to directly perform model selection using Grid Search for the optimal hyperparameters of the model This is the topic of the next section Tuning the hyperparameters of an estimator

332 Tuning the hyperparameters of an estimator

Hyperparameters are parameters that are not directly learnt within estimators In scikitlearn they are passed as arguments to the constructor of the estimator classes Typical examples include Ckernel andgamma for Support Vector Classifier alpha for Lasso etc

It is possible and recommended to search the hyperparameter space for the best cross validation score

Any parameter provided when constructing an estimator may be optimized in this manner Specifically to find the names and current values for all parameters for a given estimator use

estimatorgetparams

A search consists of

- an estimator regressor or classifier such as sklearnsvmSVC
- a parameter space
- a method for searching or sampling candidates
- a crossvalidation scheme and
- ascore function

Some models allow for specialized efficient parameter search strategies outlined below Two generic approaches to sampling search candidates are provided in scikitlearn for given values GridSearchCV exhaustively considers all parameter combinations while RandomizedSearchCV can sample a given number of candidates from a parameter space with a specified distribution After describing these tools we detail best practice applicable to both approaches Note that it is common that a small subset of those parameters can have a large impact on the predictive or computation performance of the model while others can be left to their default values It is recommended to read the docstring of the estimator class to get a finer understanding of their expected behavior possibly by reading the enclosed reference to the literature

Exhaustive Grid Search

The grid search provided by GridSearchCV exhaustively generates candidates from a grid of parameter values specified with the paramgrid parameter For instance the following paramgrid

paramgrid

C 1 10 100 1000 kernel linear

C 1 10 100 1000 gamma 0001 00001 kernel rbf

scikitlearn user guide Release 0213

specifies that two grids should be explored one with a linear kernel and C values in 1 10 100 1000 and the second one with an RBF (Radial Basis Function) kernel and the crossproduct of C values ranging in 1 10 100 1000 and gamma values in 0001 00001

TheGridSearchCV instance implements the usual estimator API (Application Programming Interface) when “fitting” it on a dataset all the possible combinations of parameter values are evaluated and the best combination is retained

Examples

- See Parameter estimation using grid search with crossvalidation for an example of Grid Search computation on the digits dataset
- See Sample pipeline for text feature extraction and evaluation for an example of Grid Search coupling parameters from a text documents feature extractor ngram count vectorizer and TFIDF transformer with a classifier here a linear SVM (Support Vector Machine) trained with SGD with either elastic net or L2 penalty using a pipeline Pipeline instance
- See Nested versus nonnested crossvalidation for an example of Grid Search within a cross validation loop on the iris dataset This is the best practice for evaluating the performance of a model with grid search
- See Demonstration of multimetric evaluation on crossvalscore and GridSearchCV for an example of GridSearchCV being used to evaluate multiple metrics simultaneously
- See Balance model complexity and crossvalidated score for an example of using refitcallable in interface inGridSearchCV The example shows how this interface adds certain amount of flexibility in identifying the “best” estimator This interface can also be used in multiple metrics evaluation

Randomized Parameter Optimization

While using a grid of parameter settings is currently the most widely used method for parameter optimization other search methods have more favourable properties RandomizedSearchCV implements a randomized search over parameters where each setting is sampled from a distribution over possible parameter values This has two main benefits over an exhaustive search

- A budget can be chosen independent of the number of parameters and possible values
 - Adding parameters that do not influence the performance does not decrease efficiency
- Specifying how parameters should be sampled is done using a dictionary very similar to specifying parameters for GridSearchCV Additionally a computation budget being the number of sampled candidates or sampling iterations is specified using the niter parameter For each parameter either a distribution over possible values or a list of discrete choices which will be sampled uniformly can be specified

```
C scipystatsexpon scale100 gamma scipystatsexpon scale1
kernel rbf classweightbalanced None
```

This example uses the scipystats module which contains many useful distributions for sampling parameters such as expon gamma uniform orrandint In principle any function can be passed that provides a rvs random variate sample method to sample a value A call to the rvs function should provide independent random samples from possible parameter values on consecutive calls

Warning The distributions in scipystats prior to version scipy 016 do not allow specifying a random state Instead they use the global numpy random state that can be seeded via nprandom seed or set using nprandomsetstate However beginning scikitlearn 018 the sklearn

33 Model selection and evaluation 449

scikitlearn user guide Release 0.21.3

modelselection module sets the random state provided by the user if scipy 0.16 is also available

For continuous parameters such as C above it is important to specify a continuous distribution to take full advantage of the randomization This way increasing niter will always lead to a finer search

Examples

- Comparing randomized search and grid search for hyperparameter estimation compares the usage and efficiency of randomized search and grid search

- Bergstra J and Bengio Y Random search for hyperparameter optimization The Journal of Machine Learning Research 2012

Tips for parameter search

Specifying an objective metric

By default parameter search uses the score function of the estimator to evaluate a parameter setting These are sklearn.metrics.accuracy_score for classification and sklearn.metrics.r2_score for regression

For some applications other scoring functions are better suited for example in unbalanced classification the accuracy score is often uninformative An alternative scoring function can be specified via the scoring parameter to GridSearchCV RandomizedSearchCV and many of the specialized crossvalidation tools described below

See The scoring parameter defining model evaluation rules for more details

Specifying multiple metrics for evaluation

GridSearchCV and RandomizedSearchCV allow specifying multiple metrics for the scoring parameter

Multimetric scoring can either be specified as a list of strings of predefined scorer names or a dict mapping the scorer name to the scorer function and/or the predefined scorer names See Using multiple metric evaluation for more details

When specifying multiple metrics the refit parameter must be set to the metric string for which the best params will be found and used to build the best estimator on the whole dataset If the search should not be refit set refit=False Leaving refit to the default value None will result in an error when using multiple metrics

See Demonstration of multimetric evaluation on cross_val_score and GridSearchCV for an example usage

Composite estimators and parameter spaces

Pipeline chaining estimators describes building composite estimators whose parameter space can be searched with these tools

450 Chapter 3 User Guide

scikitlearn user guide Release 0213

Model selection development and evaluation

Model selection by evaluating various parameter settings can be seen as a way to use the labeled data to “train” the parameters of the grid

When evaluating the resulting model it is important to do it on heldout samples that were not seen during the grid search process it is recommended to split the data into a development set to be fed to the GridSearchCV instance and an evaluation set to compute performance metrics

This can be done by using the traintestsplits utility function

Parallelism

GridSearchCV andRandomizedSearchCV evaluate each parameter setting independently Computations can be run in parallel if your OS supports it by using the keyword njobs1 See function signature for more details

Robustness to failure

Some parameter settings may result in a failure to fit one or more folds of the data By default this will cause the entire search to fail even if some parameter settings could be fully evaluated Setting errorscore0 ornp

NaN will make the procedure robust to such failure issuing a warning and setting the score for that fold to 0 or NaN but completing the search

Alternatives to brute force parameter search

Model specific crossvalidation

Some models can fit data for a range of values of some parameter almost as efficiently as fitting the estimator for a single value of the parameter This feature can be leveraged to perform a more efficient crossvalidation used for model selection of this parameter

The most common parameter amenable to this strategy is the parameter encoding the strength of the regularizer In this case we say that we compute the regularization path of the estimator

Here is the list of such models

linearmodelElasticNetCV l1ratio eps Elastic Net model with iterative fitting along a regulariza
tion path

linearmodelLarsCV fitintercept Crossvalidated Least Angle Regression model

Parameters

l1ratio float or array of floats optional float between 0 and 1 passed to ElasticNet scal

ing between l1 and l2 penalties For l1ratio 0 the penalty is an L2 penalty For

l1ratio 1 it is an L1 penalty For 0 l1ratio 1 the penalty is a com

ination of L1 and L2 This parameter can be a list in which case the different values are

tested by crossvalidation and the one giving the best prediction score is used Note that a

good choice of list of values for l1ratio is often to put more values close to 1 ie Lasso

and less close to 0 ie Ridge as in 1 5 7 9 95 99 1

eps float optional Length of the path eps1e3 means that alphas min alphas max

1e3

alphas int optional Number of alphas along the regularization path used for each l1ratio

alphas numpy array optional List of alphas where to compute the models If None alphas are

set automatically

fitintercept boolean whether to calculate the intercept for this model If set to false no

intercept will be used in calculations eg data is expected to be already centered

normalize boolean optional default False This parameter is ignored when

fitintercept is set to False If True the regressors X will be normalized be

fore regression by subtracting the mean and dividing by the l2norm If you wish to

standardize please use sklearnpreprocessingStandardScaler before

calling fit on an estimator with normalizeFalse

precompute True False 'auto' arraylike Whether to use a precomputed Gram matrix to

speed up calculations If set to auto let us decide The Gram matrix can also be passed

as argument

maxiter int optional The maximum number of iterations

tol float optional The tolerance for the optimization if the updates are smaller than tol the

optimization code checks the dual gap for optimality and continues until it is smaller than

tol

cv int crossvalidation generator or an iterable optional Determines the crossvalidation split

ting strategy Possible inputs for cv are

- None to use the default 3fold crossvalidation

scikitlearn user guide Release 0213

- integer to specify the number of folds
- CV (Cross-Validation) splitter
- An iterable yielding train test splits as arrays of indices

For integerNone inputs KFold is used

Refer User Guide for the various crossvalidation strategies that can be used here

Changed in version 020 cvdefault value if None will change from 3fold to 5fold in v022

copyX boolean optional default True If True X will be copied else it may be overwritten

verbose bool or integer Amount of verbosity

njobs int or None optional defaultNone Number of CPUs to use during the cross valida

tionNone means 1 unless in a joblibparallelbackend context1means using

all processors See Glossary for more details

positive bool optional When set to True forces the coefficients to be positive

randomstate int RandomState instance or None optional default None The seed of the

pseudo random number generator that selects a random feature to update If int ran

domstate is the seed used by the random number generator If RandomState instance

randomstate is the random number generator If None the random number generator is

the RandomState instance used by nprandom Used when selection 'random'

selection str default 'cyclic' If set to 'random' a random coefficient is updated every iteration

rather than looping over features sequentially by default This setting to 'random' often

leads to significantly faster convergence especially when tol is higher than 1e4

Attributes

alpha float The amount of penalization chosen by cross validation

l1ratio float The compromise between l1 and l2 penalization chosen by cross validation

coef array shape nfeatures ntargets nfeatures Parameter vector w in the cost func

tion formula

intercept float array shape ntargets nfeatures Independent term in the decision func

tion

msepath array shape nl1ratio nalpha nfolds Mean square error for the test set on

each fold varying l1ratio and alpha

alphas numpy array shape nalphas or nl1ratio nalphas The grid of alphas used for

fitting for each l1ratio

niter int number of iterations run by the coordinate descent solver to reach the specified

tolerance for the optimal alpha

ElasticNet

Notes

For an example see exampleslinearmodelplotlassomodelselectionpy

33 Model selection and evaluation 453

scikitlearn user guide Release 0213

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran contiguous numpy array

The parameter l1ratio corresponds to alpha in the glmnet R package while alpha corresponds to the lambda parameter in glmnet More specifically the optimization objective is

$$\frac{1}{2} \sum_{i=1}^n \text{samples } y_i - \sum_{j=1}^p \text{Xw}_j^2$$

$$\alpha \text{ l1ratio } w_1$$

$$0.5 \alpha \text{ l1ratio } w_2^2$$

If you are interested in controlling the L1 and L2 penalty separately keep in mind that this is equivalent to

$$\alpha L_1 + \beta L_2$$

for
 α α β and $\text{l1ratio} = \alpha / (\alpha + \beta)$

Methods

fit(self, X, y) Fit linear model with coordinate descent

get_params(self, deep=True) Get parameters for this estimator

path(X, y, l1_ratio, eps, n_alphas) Compute elastic net path with coordinate descent

predict(self, X) Predict using the linear model

score(self, X, y, sample_weight) Returns the coefficient of determination R² of the prediction

set_params(self, **kwargs) Set the parameters of this estimator

init(self, l1_ratio=0.5, eps=0.0001, n_alphas=100, alphas=None, fit_intercept=True, normal

ize=False, precompute='auto', max_iter=1000, tol=0.00001, cv='warn', copy_X=True, ver

bose=0, n_jobs=None, positive=False, random_state=None, selection='cyclic')

fit(self, X, y)

Fit linear model with coordinate descent

scikitlearn user guide Release 0213

Fit is on grid of alphas and best alpha estimated by crossvalidation

Parameters

Xarraylike shape nsamples nfeatures Training data Pass directly as Fortran contiguous data to avoid unnecessary memory duplication If y is monooutput X can be sparse

yarraylike shape nsamples or nsamples ntargets Target values

getparams selfdeepTrue

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

staticpathXyl1ratio05 eps0001 nalphas100 alphasNone precompute'auto'

XyNone copyXTrue coefinitNone verboseFalse returnniterFalse posi

tiveFalse checkinputTrue params

Compute elastic net path with coordinate descent

The elastic net optimization function varies for mono and multioutputs

For monooutput tasks it is

1 2nsamples y Xw22

alpha l1ratio w1

05alpha1 l1ratio w22

For multioutput tasks it is

1 2 nsamples Y XWFro2

alpha l1ratio W21

05alpha1 l1ratio WFro2

Where

W21 sumi sqrtsumj wij2

ie the sum of norm of each row

Read more in the User Guide

Parameters

Xarraylike shape nsamples nfeatures Training data Pass directly as Fortran

contiguous data to avoid unnecessary memory duplication If yis monooutput then X

can be sparse

yndarray shape nsamples or nsamples noutputs Target values

l1ratio float optional float between 0 and 1 passed to elastic net scaling between l1 and

l2 penalties l1ratio1 corresponds to the Lasso

eps float Length of the path eps1e3 means that alphamin alphamax

1e3

nalphas int optional Number of alphas along the regularization path

33 Model selection and evaluation 455

scikitlearn user guide Release 0213

alphas ndarray optional List of alphas where to compute the models If None alphas are set automatically

precompute True False 'auto' arraylike Whether to use a precomputed Gram matrix to speed up calculations If set to auto let us decide The Gram matrix can also be passed as argument

Xyarraylike optional Xy npdotXT y that can be precomputed It is useful only when the Gram matrix is precomputed

copyX boolean optional default True If True X will be copied else it may be over written

coefinit array shape nfeatures None The initial values of the coefficients

verbose bool or integer Amount of verbosity

returnniter bool whether to return the number of iterations or not

positive bool default False If set to True forces coefficients to be positive Only allowed whenydim 1

checkinput bool default True Skip input validation checks including the Gram matrix when provided assuming there are handled by the caller when checkinputFalse

params kwargs keyword arguments passed to the coordinate descent solver

Returns

alphas array shape nalphas The alphas along the path where models are computed

coefs array shape nfeatures nalphas or noutputs nfeatures nalphas Coefficients along the path

dualgaps array shape nalphas The dual gaps at the end of the optimization for each alpha

niters arraylike shape nalphas The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha Is returned when returnniter is set to True

`predictselfX`

Predict using the linear model

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures Samples

Returns

456 Chapter 3 User Guide

scikitlearn user guide Release 0213

Carray shape nsamples Returns predicted values

scoreselfXysampleweightNone

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

2sum and v is the total sum of squares $y_{true} - y_{truemean}$ 2sum The best possible score

is 10 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 00

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may

be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage

from version 023 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form componentparameter so that it's possible to update each component

of a nested object

Returns

self

sklearnlinearmodel LarsCV

Parameters

fitintercept boolean whether to calculate the intercept for this model If set to false no

intercept will be used in calculations eg data is expected to be already centered

33 Model selection and evaluation 457

scikitlearn user guide Release 0213

verbose boolean or integer optional Sets the verbosity amount
maxiter integer optional Maximum number of iterations to perform
normalize boolean optional default True This parameter is ignored when fitintercept
is set to False If True the regressors X will be normalized before regression by sub
tracting the mean and dividing by the l2norm If you wish to standardize please use
sklearnpreprocessingStandardScaler before calling fit on an estimator
withnormalizeFalse
precompute True False 'auto' arraylike Whether to use a precomputed Gram matrix to
speed up calculations If set to auto let us decide The Gram matrix cannot be passed
as argument since we will use only subsets of X
cvint crossvalidation generator or an iterable optional Determines the crossvalidation split
ting strategy Possible inputs for cv are
• None to use the default 3fold crossvalidation
• integer to specify the number of folds
• CV (Cross-Validation) splitter
• An iterable yielding train test splits as arrays of indices
For integerNone inputs KFold is used
Refer User Guide for the various crossvalidation strategies that can be used here
Changed in version 020 cvdefault value if None will change from 3fold to 5fold in
v022
maxnalphas integer optional The maximum number of points on the path used to compute
the residuals in the crossvalidation
njobs int or None optional defaultNone Number of CPUs to use during the cross valida
tionNone means 1 unless in a joblibparallelbackend context1means using
all processors See Glossary for more details
eps float optional The machineprecision regularization in the computation of the Cholesky
diagonal factors Increase this for very illconditioned systems
copyX boolean optional default True If True X will be copied else it may be overwritten
positive boolean defaultFalse Restrict coefficients to be 0 Be aware that you might
want to remove fitintercept which is set True by default
Deprecated since version 020 The option is broken and deprecated It will be removed in
v022
Attributes
coef array shape nfeatures parameter vector w in the formulation formula
intercept float independent term in decision function
coefpath array shape nfeatures nalphas the varying values of the coefficients along the
path
alpha float the estimated regularization parameter alpha
alphas array shape nalphas the different values of alpha along the path
cvalphas array shape ncvalphas all the values of alpha along the path for the different
folds

scikitlearn user guide Release 0213

msepath array shape nfold ncvalphas the mean square error on leftout for each fold
along the path alpha values given by cvalphas

niter arraylike or int the number of iterations run by Lars with the optimal alpha

See also

larspath

Lasso

LassoLars

LassoCV

LassoLarsCV

sklearn.decomposition.sparse_encode

Notes

For an example see `examples/linear_model/plot_lasso_coordinated_descent_path.py`

To avoid unnecessary memory duplication the `X` argument of the fit method should be directly passed as a

Fortran contiguous numpy array

Note that in certain cases the Lars solver may be significantly faster to implement this functionality. In

particular linear interpolation can be used to retrieve model coefficients between the values output by

`larspath`

Examples

Comparing `lassopath` and `larspath` with interpolation

```
X = np.array([2, 31, 23, 54, 43])
```

```
y = np.array([2, 31])
```

Use `lassopath` to compute a coefficient path

```
coef_path = lassopath(X, y, alphas=[5, 1, 5])
```

```
print(coef_path
```

```
0.0 0.046874778
```

```
0.2159048 0.04425765 0.23689075
```

Now use `larspath` and 1D linear interpolation to compute the

same path

```
from sklearn.linear_model import larspath
```

```
alphas, active, coef_path_lars = larspath(X, y, method='lasso')
```

```
from scipy import interpolate
```

```
coef_path_continuous = interpolate.interp1d(alphas, 1,
```

```
coef_path_lars)
```

```
print(coef_path_continuous(5, 1, 5))
```

```
0.0 0.046915237
```

```
0.2159048 0.04425765 0.23668876
```

```
predict_self(X)
```

Predict using the linear model

Parameters

`X`: array-like or sparse matrix shape `(n_samples, n_features)` Samples

Returns

`C`: array shape `(n_samples,)` Returns predicted values

33 Model selection and evaluation 465

scikitlearn user guide Release 0213

scoreselfXysampleweightNone

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

2sum and v is the total sum of squares $y_{true} - y_{truemean}$ 2sum The best possible score

is 10 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 00

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may

be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage

from version 023 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form componentparameter so that it's possible to update each component

of a nested object

Returns

self

Examples using sklearnlinearmodelLassoCV

Crossvalidated Lasso using the LARS algorithm

466 Chapter 3 User Guide

scikitlearn user guide Release 0213

See glossary entry for crossvalidation estimator

The optimization objective for Lasso is

$\frac{1}{2} \sum_{i=1}^n (y_i - \sum_{j=1}^p w_j x_{ij})^2 + \alpha \sum_{j=1}^p |w_j|$

Read more in the User Guide

Parameters

fitintercept boolean whether to calculate the intercept for this model If set to false no

intercept will be used in calculations eg data is expected to be already centered

verbose boolean or integer optional Sets the verbosity amount

maxiter integer optional Maximum number of iterations to perform

normalize boolean optional default True This parameter is ignored when fitintercept

is set to False If True the regressors X will be normalized before regression by sub

tracting the mean and dividing by the l2norm If you wish to standardize please use

sklearnpreprocessingStandardScaler before calling fit on an estimator

withnormalizeFalse

precompute True False 'auto' Whether to use a precomputed Gram matrix to speed up

calculations If set to auto let us decide The Gram matrix cannot be passed as argument

since we will use only subsets of X

cvint crossvalidation generator or an iterable optional Determines the crossvalidation split

ting strategy Possible inputs for cv are

- None to use the default 3fold crossvalidation

- integer to specify the number of folds

- CV (Cross-Validation) splitter

- An iterable yielding train test splits as arrays of indices

For integerNone inputs KFold is used

Refer User Guide for the various crossvalidation strategies that can be used here

Changed in version 020 cvdefault value if None will change from 3fold to 5fold in

v022

maxnalphas integer optional The maximum number of points on the path used to compute

the residuals in the crossvalidation

njobs int or None optional defaultNone Number of CPUs to use during the cross valida

tionNone means 1 unless in a joblibparallelbackend context1means using

all processors See Glossary for more details

eps float optional The machineprecision regularization in the computation of the Cholesky

diagonal factors Increase this for very illconditioned systems

copyX boolean optional default True If True X will be copied else it may be overwritten

positive boolean defaultFalse Restrict coefficients to be ≥ 0 Be aware that you might

want to remove fitintercept which is set True by default Under the positive restriction the

model coefficients do not converge to the ordinaryleastquares solution for small values

of alpha Only coefficients up to the smallest alpha value α_{min} α_{max} α_{1dof}

min when fitpathTrue reached by the stepwise LarsLasso algorithm are typically in

congruence with the solution of the coordinate descent Lasso estimator As a consequence

33 Model selection and evaluation 467

scikitlearn user guide Release 0213

using LassoLarsCV only makes sense for problems where a sparse solution is expected and/or reached

Attributes

coef array shape nfeatures parameter vector w in the formulation formula

intercept float independent term in decision function

coefpath array shape nfeatures nalphas the varying values of the coefficients along the path

alpha float the estimated regularization parameter alpha

alphas array shape nalphas the different values of alpha along the path

cvalphas array shape ncvalphas all the values of alpha along the path for the different folds

msepath array shape nfolds ncvalphas the mean square error on leftout for each fold along the path alpha values given by cvalphas

niter arraylike or int the number of iterations run by Lars with the optimal alpha

See also

larspath LassoLars LarsCV LassoCV

Notes

The object solves the same problem as the LassoCV object However unlike the LassoCV it find the relevant alphas values by itself In general because of this property it will be more stable However it is more fragile to heavily multicollinear datasets

It is more efficient than the LassoCV if only a small number of features are selected compared to the total number for instance if there are very few samples compared to the number of features

Examples

from sklearn.linear_model import LassoLarsCV

from sklearn.datasets import make_regression

X, y = make_regression(n_samples=100, n_features=10, noise=0.1, random_state=0)

reg = LassoLarsCV(cv=5).fit(X, y)

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

$2sum$ and v is the total sum of squares $y_{true} - y_{truemean}$ $2sum$ The best possible score

is 10 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 00

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may

be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

scikitlearn user guide Release 0213

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage from version 023 to keep consistent with metricsr2score This will influence the score method of all the multioutput regressors except for multioutputMultiOutputRegressor To specify the default value manually and avoid the warning please either call metricsr2score directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses multioutputuniformaverage setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form componentparameter so that it's possible to update each component of a nested object

Returns

self

njobsNone verbose0 refitTrue in

terceptscaling10 multiclass'warn'

randomstateNone l1ratiosNone

Logistic Regression CV (Cross-Validation) aka logit MaxEnt classifier

See glossary entry for crossvalidation estimator

This class implements logistic regression using liblinear newtoncg sag of lbfgs optimizer The newtoncg sag and lbfgs solvers support only L2 regularization with primal formulation The liblinear solver supports both L1 and L2 regularization with a dual formulation only for the L2 penalty ElasticNet penalty is only supported by the saga solver

For the grid of Csvalues and l1ratios values the best hyperparameter is selected by the crossvalidator

StratifiedKFold but it can be changed using the cvparameter The 'newtoncg' 'sag' 'saga' and 'lbfgs'

solvers can warmstart the coefficients see Glossary

Read more in the User Guide

Parameters

Cslist of floats or int optional default10 Each of the values in Cs describes the inverse of regularization strength If Cs is as an int then a grid of Cs values are chosen in a logarithmic scale between 1e4 and 1e4 Like in support vector machines smaller values specify stronger regularization

fitintercept bool optional defaultTrue Specifies if a constant aka bias or intercept should be added to the decision function

470 Chapter 3 User Guide

scikitlearn user guide Release 0213

cvint or crossvalidation generator optional defaultNone The default crossvalidation generator used is Stratified KFold If an integer is provided then it is the number of folds used See the module sklearnmodelselection module for the list of possible crossvalidation objects

Changed in version 020 cvdefault value if None will change from 3fold to 5fold in v022

dual bool optional defaultFalse Dual or primal formulation Dual formulation is only implemented for l2 penalty with liblinear solver Prefer dualFalse when nsamples nfeatures

penalty str 'l1' 'l2' or 'elasticnet' optional default'l2' Used to specify the norm used in the penalization The 'newtoncg' 'sag' and 'lbfgs' solvers support only l2 penalties 'elasticnet' is only supported by the 'saga' solver

scoring callable or None optional defaultNone A string see model evaluation documentation or a scorer callable object function with signature scorer(estimator, X, y) For a list of scoring functions that can be used look at sklearnmetrics The default scoring option used is 'accuracy'

solver str 'newtoncg' 'lbfgs' 'liblinear' 'sag' 'saga' optional default'lbfgs' Algorithm to use in the optimization problem

- For small datasets 'liblinear' is a good choice whereas 'sag' and 'saga' are faster for large ones
- For multiclass problems only 'newtoncg' 'sag' 'saga' and 'lbfgs' handle multinomial loss 'liblinear' is limited to oneversusrest schemes
- 'newtoncg' 'lbfgs' and 'sag' only handle L2 penalty whereas 'liblinear' and 'saga' handle L1 penalty
- 'liblinear' might be slower in LogisticRegressionCV because it does not handle warm starting

Note that 'sag' and 'saga' fast convergence is only guaranteed on features with approximately the same scale You can preprocess the data with a scaler from sklearnpreprocessing

New in version 017 Stochastic Average Gradient descent solver

New in version 019 SAGA solver

tol float optional default1e4 Tolerance for stopping criteria

max_iter int optional default100 Maximum number of iterations of the optimization algorithm

class_weight dict or 'balanced' optional defaultNone Weights associated with classes in the form {class_label: weight} If not given all classes are supposed to have weight one

The "balanced" mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as $\frac{n_{\text{samples}}}{n_{\text{classes}} \times \text{np.bincount(y)}}$

Note that these weights will be multiplied with sample_weight passed through the fit method if sample_weight is specified

New in version 017 class_weight 'balanced'

33 Model selection and evaluation 471

scikitlearn user guide Release 0213

njobs int or None optional defaultNone Number of CPU cores used during the cross validation loop None means 1 unless in a joblibparallelbackend context1 means using all processors See Glossary for more details

verbose int optional default0 For the 'liblinear' 'sag' and 'lbfgs' solvers set verbose to any positive number for verbosity

refit bool optional defaultTrue If set to True the scores are averaged across all folds and the coefs and the C that corresponds to the best score is taken and a final refit is done using these parameters Otherwise the coefs intercepts and C that correspond to the best scores across folds are averaged

interceptscaling float optional default1 Useful only when the solver 'liblinear' is used and selffitintercept is set to True In this case x becomes x selfinterceptscaling ie a "synthetic" feature with constant value equal to interceptscaling is appended to the instance vector The intercept becomes interceptscaling

syntheticfeatureweight

Note the synthetic feature weight is subject to l1l2 regularization as all other features To lessen the effect of regularization on synthetic feature weight and therefore on the intercept interceptscaling has to be increased

multiclass str 'ovr' 'multinomial' 'auto' optional default'ovr' If the option chosen is 'ovr' then a binary problem is fit for each label For 'multinomial' the loss minimised is the multinomial loss fit across the entire probability distribution even when the data is binary 'multinomial' is unavailable when solver'liblinear' 'auto' selects 'ovr' if the data is binary or if solver'liblinear' and otherwise selects 'multinomial'

New in version 018 Stochastic Average Gradient descent solver for 'multinomial' case Changed in version 020 Default will change from 'ovr' to 'auto' in 022

randomstate int RandomState instance or None optional defaultNone If int randomstate is the seed used by the random number generator If RandomState instance randomstate is the random number generator If None the random number generator is the RandomState instance used by nprandom

l1ratios list of float or None optional defaultNone The list of ElasticNet mixing parameter with0 l1ratio 1 Only used if penaltyelasticnet A value of 0 is equivalent to using penaltyl2 while 1 is equivalent to using penaltyl1 For0 l1ratio 1 the penalty is a combination of L1 and L2

Attributes

classes array shape nclasses A list of class labels known to the classifier

coef array shape 1 nfeatures or nclasses nfeatures Coefficient of the features in the decision function

coef is of shape 1 nfeatures when the given problem is binary

intercept array shape 1 or nclasses Intercept aka bias added to the decision function

Iffitintercept is set to False the intercept is set to zero intercept is of shape1 when the problem is binary

Cs array shape ncs Array of C ie inverse of regularization parameter values used for crossvalidation

l1ratios array shape nl1ratios Array of l1ratios used for crossvalidation If no l1ratio is used ie penalty is not 'elasticnet' this is set to None

472 Chapter 3 User Guide

scikitlearn user guide Release 0213

coefspaths array shape n folds ncs nfeatures or n folds ncs nfeatures 1 dict with classes as the keys and the path of coefficients obtained during crossvalidating across each fold and then across each Cs after doing an OvR for the corresponding class as values If the 'multiclass' option is set to 'multinomial' then the coefspaths are the coefficients corresponding to each class Each dict value has shape n folds ncs nfeatures or n folds ncs nfeatures 1 depending on whether the intercept is fit or not If penaltyelasticnet the shape is n folds ncs n l1ratios nfeatures or n folds ncs n l1ratios nfeatures 1 scores dict dict with classes as the keys and the values as the grid of scores obtained during crossvalidating each fold after doing an OvR for the corresponding class If the 'multiclass' option given is 'multinomial' then the same scores are repeated across all classes since this is the multinomial class Each dict value has shape n folds ncs or n folds ncs n l1ratios if penaltyelasticnet C array shape nclasses or nclasses 1 Array of C that maps to the best scores across every class If refit is set to False then for each class the best C is the average of the C's that correspond to the best scores for each fold C is of shape nclasses when the problem is binary l1ratio array shape nclasses or nclasses 1 Array of l1ratio that maps to the best scores across every class If refit is set to False then for each class the best l1ratio is the average of the l1ratio's that correspond to the best scores for each fold l1ratio is of shape nclasses when the problem is binary niter array shape nclasses n folds ncs or 1 n folds ncs Actual number of iterations for all classes folds and Cs In the binary or multinomial cases the first dimension is equal to 1 If penaltyelasticnet the shape is nclasses n folds ncs n l1ratios or 1 n folds ncs n l1ratios

`fitself X y sampleweight` Fit the model according to the given training data

`getparams self deep` Get parameters for this estimator

`predict self X` Predict class labels for samples in X

`predictlogproba self X` Log of probability estimates

`predictproba self X` Probability estimates

`score self X y sampleweight` Returns the score using the scoring option on the given test data and labels

`setparams self params` Set the parameters of this estimator

`sparsify self` Convert coefficient matrix to sparse format

`init selfCs10 fitinterceptTrue cv'warn' dualFalse penalty'l2' scoringNone solver'lbfgs' tol00001 maxiter100 classweightNone njobsNone verbose0 refitTrue interceptscaling10 multiclass'warn' randomstateNone l1ratiosNone`

`decisionfunction selfX`

Predict confidence scores for samples

The confidence score for a sample is the signed distance of that sample to the hyperplane

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures Samples

Returns

array shapensamples if nclasses > 2 else nsamples nclasses Confidence scores per sample class combination In the binary case confidence score for selfclasses1 where 0 means this class would be predicted

`densifyself`

Convert coefficient matrix to dense array format

Converts the coef member back to a numpyndarray This is the default format of coef and is required for fitting so calling this method is only required on models that have previously been sparsified otherwise it is a noop

Returns

self estimator

`fitselfXysampleweightNone`

Fit the model according to the given training data

Parameters

Xarraylike sparse matrix shape nsamples nfeatures Training vector where nsamples is the number of samples and nfeatures is the number of features yarraylike shape nsamples Target vector relative to X sampleweight arraylike shape nsamples optional Array of weights that are assigned to individual samples If not provided then each sample is given unit weight

Returns

self object

`getparams selfdeepTrue`

Get parameters for this estimator

Parameters

474 Chapter 3 User Guide

scikitlearn user guide Release 0213

deep boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

predictselfX

Predict class labels for samples in X

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures Samples

Returns

Carray shape nsamples Predicted class label per sample

predictlogproba selfX

Log of probability estimates

The returned estimates for all classes are ordered by the label of classes

Parameters

Xarraylike shape nsamples nfeatures

Returns

Tarraylike shape nsamples nclasses Returns the logprobability of the sample for

each class in the model where classes are ordered as they are in selfclasses

predictproba selfX

Probability estimates

The returned estimates for all classes are ordered by the label of classes

For a multiclass problem if multiclass is set to be “multinomial” the softmax function is used to find the predicted probability of each class Else use a onevsrest approach ie calculate the probability of each class assuming it to be positive using the logistic function and normalize these values across all the classes

Parameters

Xarraylike shape nsamples nfeatures

Returns

Tarraylike shape nsamples nclasses Returns the probability of the sample for each

class in the model where classes are ordered as they are in selfclasses

scoreselfXysampleweightNone

Returns the score using the scoring option on the given test data and labels

Parameters

Xarraylike shape nsamples nfeatures Test samples

yarraylike shape nsamples True labels for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float Score of selfpredictX wrt y

33 Model selection and evaluation 475

scikitlearn user guide Release 0.21.3

set_params(self, params)

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines. The latter have parameters of the form `component__parameter` so that it's possible to update each component of a nested object.

Returns

self

sparsify(self)

Convert coefficient matrix to sparse format

Converts the `coef` member to a `scipy.sparse` matrix which for `L1` regularized models can be much more memory and storage efficient than the usual `numpy.ndarray` representation. The `intercept` member is not converted.

Returns

self.estimator

Notes

For non-sparse models (ie when there are not many zeros in `coef`) this may actually increase memory usage so use this method with care. A rule of thumb is that the number of zero elements which can be computed with `coef_0sum` must be more than 50 for this to provide significant benefits.

After calling this method further fitting with the `partial_fit` method if any will not work until you call `densify`.

`sklearn.linear_model.MultiTaskElasticNetCV`

`class sklearn.linear_model.MultiTaskElasticNetCV(l1_ratio=0.5, eps=0.001, n_alphas=100,`

`alpha=None, fit_intercept=True,`

`normalize=False, max_iter=1000,`

`tol=0.0001, cv_warn=True,`

`verbose=0, n_jobs=None, random_state=None,`

`selection='cyclic')`

Multi-task L1/L2 ElasticNet with builtin cross-validation

See glossary entry for cross-validation estimator

The optimization objective for `MultiTaskElasticNet` is

$$\frac{1}{2} \|XW - Y\|_F^2 + \frac{\alpha}{2} \|W\|_1 + \frac{\lambda}{2} \|W\|_2^2$$

where

$$\|W\|_1 = \sum_i \sqrt{\sum_j w_{ij}^2}$$

ie the sum of norm of each row

Read more in the User Guide

Parameters

476 Chapter 3 User Guide

scikitlearn user guide Release 0213

`l1ratio` float or array of floats The ElasticNet mixing parameter with 0 `l1ratio` 1 For `l1ratio` 1 the penalty is an L1L2 penalty For `l1ratio` 0 it is an L2 penalty For 0 `l1ratio` 1 the penalty is a combination of L1L2 and L2 This parameter can be a list in which case the different values are tested by crossvalidation and the one giving the best prediction score is used Note that a good choice of list of values for `l1ratio` is often to put more values close to 1 ie Lasso and less close to 0 ie Ridge as in 1 5 7 9 95 99 1

`eps` float optional Length of the path `eps1e3` means that `alpha_min` `alpha_max` `1e3`

`nalphas` int optional Number of alphas along the regularization path

`alphas` arraylike optional List of alphas where to compute the models If not provided set automatically

`fitintercept` boolean whether to calculate the intercept for this model If set to false no intercept will be used in calculations eg data is expected to be already centered

`normalize` boolean optional default False This parameter is ignored when

`fitintercept` is set to False If True the regressors X will be normalized be

fore regression by subtracting the mean and dividing by the `l2norm` If you wish to

standardize please use `sklearnpreprocessingStandardScaler` before

calling `fit` on an estimator with `normalizeFalse`

`maxiter` int optional The maximum number of iterations

`tol` float optional The tolerance for the optimization if the updates are smaller than `tol` the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`

`cv` int crossvalidation generator or an iterable optional Determines the crossvalidation splitting strategy Possible inputs for `cv` are

- None to use the default 3fold crossvalidation
- integer to specify the number of folds
- CV (Cross-Validation) splitter
- An iterable yielding train test splits as arrays of indices

For integerNone inputs `KFold` is used

Refer User Guide for the various crossvalidation strategies that can be used here Changed in version 020 `cvdefault` value if None will change from 3fold to 5fold in v022

`copyX` boolean optional default True If True X will be copied else it may be overwritten

`verbose` bool or integer Amount of verbosity

`njobs` int or None optional defaultNone Number of CPUs to use during the cross validation Note that this is used only if multiple values for `l1ratio` are given None means 1 unless in a `joblibparallelbackend` context1means using all processors See Glossary for more details

`randomstate` int `RandomState` instance or None optional default None The seed of the pseudo random number generator that selects a random feature to update If int `randomstate` is the seed used by the random number generator If `RandomState` instance `randomstate` is the random number generator If None the random number generator is the `RandomState` instance used by `nprandom` Used when selection ‘random’

33 Model selection and evaluation 477

scikitlearn user guide Release 0213

selection str default 'cyclic' If set to 'random' a random coefficient is updated every iteration rather than looping over features sequentially by default This setting to 'random' often leads to significantly faster convergence especially when tol is higher than 1e4

Attributes

intercept array shape ntasks Independent term in decision function

coef array shape ntasks nfeatures Parameter vector W in the cost function formula

Note thatcoef stores the transpose of WWT

alpha float The amount of penalization chosen by cross validation

msepath array shape nalphas nfolds or nl1ratio nalphas nfolds mean square error for the test set on each fold varying alpha

alphas numpy array shape nalphas or nl1ratio nalphas The grid of alphas used for fitting for each l1ratio

l1ratio float best l1ratio obtained by crossvalidation

niter int number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha

MultiTaskElasticNetCV

ElasticNet

ElasticNetCV

Notes

For an example see `examples/linear_model/plot_lasso_coordinated_descent_path.py`

`predict_selfX`

Predict using the linear model

Parameters

Xarraylike or sparse matrix shape `nsamples nfeatures` Samples

Returns

Carray shape `nsamples` Returns predicted values

`score_selfXysampleweight`None

Returns the coefficient of determination R^2 of the prediction

The coefficient R^2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

$2sum$ and v is the total sum of squares $y_{true} - y_{truemean}$ $2sum$ The best possible score

is 1.0 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R^2 score of 0.0

Parameters

Xarraylike shape `nsamples nfeatures` Test samples For some estimators this may

be a precomputed kernel matrix instead shape `nsamples nsamplesfitted` where

`nsamplesfitted` is the number of samples used in the fitting for the estimator

yarraylike shape `nsamples` or `nsamples noutputs` True values for X

sampleweight arraylike shape `nsamples` optional Sample weights

Returns

score float R^2 of `self.predictX` wrt y

Notes

The R^2 score used when calling `score` on a regressor will use `multioutputuniformaverage`

from version 0.23 to keep consistent with `metricsr2score` This will influence the score

method of all the multioutput regressors except for `MultiOutputRegressor`

To specify the default value manually and avoid the warning please either call `metricsr2score`

directly or make a custom scorer with `metricsmakescorer` the builtin scorer `r2` uses

`multioutputuniformaverage`

`set_params` `self.params`

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form `componentparameter` so that it's possible to update each component

of a nested object

path(X, y, eps=None, alphas=None) Compute Lasso path with coordinate descent
predict(X) Predict using the linear model
score(X, y, sample_weight=None) Returns the coefficient of determination R2 of the prediction
set_params(**params) Set the parameters of this estimator
init(self, eps=0.001, n_alphas=100, alphas=None, fit_intercept=True, normalize=False, max_iter=1000, tol=0.0001, copy_X=True, cv='warn', verbose=False, n_jobs=None, random_state=None, selection='cyclic')
fit(X, y) Fit linear model with coordinate descent
Fit is on grid of alphas and best alpha estimated by crossvalidation
```

Parameters

```
X: array-like shape (n_samples, n_features) Training data Pass directly as Fortran contiguous data to avoid unnecessary memory duplication If y is mono-output X can be sparse
y: array-like shape (n_samples) or (n_samples, n_targets) Target values
get_params(deep=True) Get parameters for this estimator
```

Parameters

```
deep: boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators
Returns
params: mapping of string to any Parameter names mapped to their values
static_path(X, eps=0.001, n_alphas=100, alphas=None, precompute='auto', Xy=None, copy_X=True, coef_init=None, verbose=False, return_niter=False, positive=False)
params
```

```
Compute Lasso path with coordinate descent
484 Chapter 3 User Guide
```

scikitlearn user guide Release 0213

The Lasso optimization function varies for mono and multioutputs

For monooutput tasks it is

1 2 nsamples y Xw22 alpha w1

For multioutput tasks it is

1 2 nsamples Y XW2Fro alpha W21

Where

W21 sumi sqrtsumj wij2

ie the sum of norm of each row

Read more in the User Guide

Parameters

Xarraylike sparse matrix shape nsamples nfeatures Training data Pass directly as Fortrancontiguous data to avoid unnecessary memory duplication If yis monooutput thenXcan be sparse

yndarray shape nsamples or nsamples noutputs Target values

eps float optional Length of the path eps1e3 means that alphamin

alphamax 1e3

nalphas int optional Number of alphas along the regularization path

alphas ndarray optional List of alphas where to compute the models If None alphas are set automatically

precompute True False 'auto' arraylike Whether to use a precomputed Gram matrix to speed up calculations If set to auto let us decide The Gram matrix can also be passed as argument

Xyarraylike optional Xy npdotXT y that can be precomputed It is useful only when the Gram matrix is precomputed

copyX boolean optional default True If True X will be copied else it may be over written

coefinit array shape nfeatures None The initial values of the coefficients

verbose bool or integer Amount of verbosity

returnniter bool whether to return the number of iterations or not

positive bool default False If set to True forces coefficients to be positive Only allowed whenyndim 1

params kwargs keyword arguments passed to the coordinate descent solver

Returns

alphas array shape nalphas The alphas along the path where models are computed

coefs array shape nfeatures nalphas or noutputs nfeatures nalphas Coefficients

along the path

dualgaps array shape nalphas The dual gaps at the end of the optimization for each alpha

33 Model selection and evaluation 485

scikitlearn user guide Release 0213

niters arraylike shape nalphas The number of iterations taken by the coordinate de
scent optimizer to reach the specified tolerance for each alpha

larspath

Lasso

LassoLars

LassoCV

LassoLarsCV

sklearn.decomposition.sparse_encode

Notes

For an example see `examples/linear_model/plot_lasso_coordinatedescent_path.py`

To avoid unnecessary memory duplication the `X` argument of the fit method should be directly passed as a
Fortran contiguous numpy array

Note that in certain cases the Lars solver may be significantly faster to implement this functionality In
particular linear interpolation can be used to retrieve model coefficients between the values output by
`larspath`

Examples

Comparing `lassopath` and `larspath` with interpolation

```
X = np.array([2, 31, 23, 54, 43])
y = np.array([2, 31])
# Use lassopath to compute a coefficient path
coef_path = lassopath(X, y, alphas=5)
print(coef_path)
# 0 0 0.46874778
# 0.2159048 0.4425765 0.23689075
```

Now use `larspath` and 1D linear interpolation to compute the
same path

```
from sklearn.linear_model import larspath
alphas = active_coef_path_lars(larspath(X, y, method='lasso'))
from scipy import interpolate
coef_path_continuous = interpolate.interp1d(alphas,
coef_path_lars)
print(coef_path_continuous(5))
# 0 0 0.46915237
# 0.2159048 0.4425765 0.23668876
```

`predict_self(X)`

Predict using the linear model

Parameters

`X` arraylike or sparse matrix shape `n_samples n_features` Samples

Returns

486 Chapter 3 User Guide

scikitlearn user guide Release 0213

Carray shape nsamples Returns predicted values

scoreselfXysampleweightNone

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

2sum and v is the total sum of squares $y_{true} - y_{true\text{mean}}$ 2sum The best possible score

is 10 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 00

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may

be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage

from version 023 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form componentparameter so that it's possible to update each component

of a nested object

Returns

self

sklearnlinearmodel OrthogonalMatchingPursuitCV

classsklearnlinearmodel OrthogonalMatchingPursuitCV copyTrue fitinterceptTrue

normalizeTrue

maxiterNone cv'warn'

njobsNone verboseFalse

Crossvalidated Orthogonal Matching Pursuit model OMP

See glossary entry for crossvalidation estimator

Read more in the User Guide

Parameters

copy bool optional Whether the design matrix X must be copied by the algorithm A false

value is only helpful if X is already Fortranordered otherwise a copy is made anyway

33 Model selection and evaluation 487

scikitlearn user guide Release 0213

fitintercept boolean optional whether to calculate the intercept for this model If set to false no intercept will be used in calculations eg data is expected to be already centered

normalize boolean optional default True This parameter is ignored when fitintercept is set to False If True the regressors X will be normalized before regression by subtracting the mean and dividing by the l2norm If you wish to standardize please use sklearnpreprocessingStandardScaler before calling fit on an estimator

withnormalizeFalse

maxiter integer optional Maximum numbers of iterations to perform therefore maximum features to include 10 of nfeatures but at least 5 if available

cvint crossvalidation generator or an iterable optional Determines the crossvalidation splitting strategy Possible inputs for cv are

- None to use the default 3fold crossvalidation
- integer to specify the number of folds
- CV (Cross-Validation) splitter
- An iterable yielding train test splits as arrays of indices

For integerNone inputs KFold is used

Refer User Guide for the various crossvalidation strategies that can be used here

Changed in version 020 cvdefault value if None will change from 3fold to 5fold in v022

njobs int or None optional defaultNone Number of CPUs to use during the cross validationNone means 1 unless in a joblibparallelbackend context1means using all processors See Glossary for more details

verbose boolean or integer optional Sets the verbosity amount

Attributes

intercept float or array shape ntargets Independent term in decision function

coef array shape nfeatures or ntargets nfeatures Parameter vector w in the problem formulation

nnonzerocoefs int Estimated number of nonzero coefficients giving the best mean squared error over the crossvalidation folds

niter int or arraylike Number of active features across every target for the model refit with the best hyperparameters got by crossvalidating across all folds

490 Chapter 3 User Guide

scikitlearn user guide Release 0213

See glossary entry for crossvalidation estimator

By default it performs Generalized CrossValidation which is a form of efficient LeaveOneOut cross validation

Read more in the User Guide

Parameters

alphas numpy array of shape nalphas Array of alpha values to try Regularization strength

must be a positive float Regularization improves the conditioning of the problem and re

duces the variance of the estimates Larger values specify stronger regularization Alpha

corresponds to C1 in other linear models such as LogisticRegression or LinearSVC If

using generalized crossvalidation alphas must be positive

fitintercept boolean Whether to calculate the intercept for this model If set to false no

intercept will be used in calculations eg data is expected to be already centered

normalize boolean optional default False This parameter is ignored when

fitintercept is set to False If True the regressors X will be normalized be

fore regression by subtracting the mean and dividing by the l2norm If you wish to

standardize please use sklearnpreprocessingStandardScaler before

callingfit on an estimator with normalizeFalse

scoring string callable or None optional default None A string see model evaluation doc

umentation or a scorer callable object function with signature scorere estimator

X y If None the negative mean squared error if cv is 'auto' or None ie when using

generalized crossvalidation and r2 score otherwise

cvint crossvalidation generator or an iterable optional Determines the crossvalidation split

ting strategy Possible inputs for cv are

- None to use the efficient LeaveOneOut crossvalidation also known as Generalized

CrossValidation

- integer to specify the number of folds

- CV (Cross-Validation) splitter

- An iterable yielding train test splits as arrays of indices

For integerNone inputs if yis binary or multiclass sklearnmodelselection

StratifiedKfold is used else sklearnmodelselectionKfold is used

Refer User Guide for the various crossvalidation strategies that can be used here

gcvmode None 'auto' 'svd' 'eigen' optional Flag indicating which strategy to use when

performing Generalized CrossValidation Options are

auto use svd ifnsamples nfeatures otherwise use eigen

svd force use of singular value decomposition of X when X is

dense eigenvalue decomposition of XTX when X issparse

eigen force computation via eigendecomposition of XXT

The 'auto' mode is the default and is intended to pick the cheaper option of the two depend

ing on the shape of the training data

storecvvalues boolean defaultFalse Flag indicating if the crossvalidation values corre

sponding to each alpha should be stored in the cvvalues attribute see below This

flag is only compatible with cvNone ie using Generalized CrossValidation

Attributes

33 Model selection and evaluation 491

scikitlearn user guide Release 0213

cvvalues array shape nsamples nalphas or shape nsamples ntargets nalphas optional Crossvalidation values for each alpha if storecvvaluesTrue and cvNone Afterfit has been called this attribute will contain the mean squared errors by default or the values of the losscorefunc function if provided in the constructor

coef array shape nfeatures or ntargets nfeatures Weight vectors

The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form componentparameter so that it's possible to update each component

of a nested object

Returns

self

Information Criterion

Some models can offer an informationtheoretic closedform formula of the optimal estimate of the regularization

parameter by computing a single regularization path instead of several when using crossvalidation

Here is the list of models benefiting from the Akaike Information Criterion AIC or the Bayesian Information Criterion

BIC for automated model selection

linearmodelLassoLarsIC criterion Lasso model fit with Lars using BIC or AIC for model se

lection

sklearnlinearmodel LassoLarsIC

classsklearnlinearmodel LassoLarsIC criterion'aic' fitinterceptTrue verboseFalse

normalizeTrue precompute'auto' maxiter500

eps2220446049250313e16 copyXTrue posi

tiveFalse

Lasso model fit with Lars using BIC or AIC for model selection

The optimization objective for Lasso is

$\frac{1}{2} \|y - Xw\|_2^2 + \alpha \|w\|_1$

AIC is the Akaike information criterion and BIC is the Bayes Information criterion Such criteria are useful to select the value of the regularization parameter by making a tradeoff between the goodness of fit and the complexity of the model A good model should explain well the data while being simple

Read more in the User Guide

33 Model selection and evaluation 497

Parameters

criterion 'bic' 'aic' The type of criterion to use

fitintercept boolean whether to calculate the intercept for this model If set to false no intercept will be used in calculations eg data is expected to be already centered

verbose boolean or integer optional Sets the verbosity amount

normalize boolean optional default True This parameter is ignored when fitintercept is set to False If True the regressors X will be normalized before regression by subtracting the mean and dividing by the l2norm If you wish to standardize please use sklearnpreprocessingStandardScaler before calling fit on an estimator

withnormalizeFalse

precompute True False 'auto' arraylike Whether to use a precomputed Gram matrix to speed up calculations If set to auto let us decide The Gram matrix can also be passed as argument

maxiter integer optional Maximum number of iterations to perform Can be used for early stopping

eps float optional The machineprecision regularization in the computation of the Cholesky diagonal factors Increase this for very illconditioned systems Unlike the tol parameter in some iterative optimizationbased algorithms this parameter does not control the tolerance of the optimization

copyX boolean optional default True If True X will be copied else it may be overwritten

positive boolean defaultFalse Restrict coefficients to be 0 Be aware that you might want to remove fitintercept which is set True by default Under the positive restriction the model coefficients do not converge to the ordinaryleastquares solution for small values of alpha Only coefficients up to the smallest alpha value α_{min} are typically in congruence with the solution of the coordinate descent Lasso estimator As a consequence using LassoLarsIC only makes sense for problems where a sparse solution is expected and/or reached

Attributes

coef array shape nfeatures parameter vector w in the formulation formula

intercept float independent term in decision function

alpha float the alpha parameter chosen by the information criterion

niter int number of iterations run by larspath to find the grid of alphas

criterion array shape nalphas The value of the information criteria 'aic' 'bic' across all alphas The alpha which has the smallest information criterion is chosen This value is larger by a factor of nsamples compared to Eqns 215 and 216 in Zou et al 2007

scoreselfXysampleweightNone

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

2sum and v is the total sum of squares $y_{true} - y_{truemean}$ 2sum The best possible score

is 10 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 00

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may

be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage

from version 023 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form componentparameter so that it's possible to update each component

of a nested object

Returns

self

500 Chapter 3 User Guide

scikitlearn user guide Release 0213

Out of Bag Estimates

When using ensemble methods base upon bagging ie generating new training sets using sampling with replacement part of the training set remains unused For each classifier in the ensemble a different part of the training set is left out

This left out portion can be used to estimate the generalization error without having to rely on a separate validation set This estimate comes “for free” as no additional data is needed and can be used for model selection

This is currently implemented in the following classes

ensembleRandomForestClassifier A random forest classifier

ensembleRandomForestRegressor A random forest regressor

ensembleExtraTreesClassifier An extratrees classifier

ensembleExtraTreesRegressor nestimators

An extratrees regressor

ensembleGradientBoostingClassifier loss

Gradient Boosting for classification

ensembleGradientBoostingRegressor loss

A random forest classifier

A random forest is a meta estimator that fits a number of decision tree classifiers on various subsamples of the dataset and uses averaging to improve the predictive accuracy and control overfitting The subsample size is always the same as the original input sample size but the samples are drawn with replacement if bootstrapTrue default

Read more in the User Guide

Parameters

nestimators integer optional default10 The number of trees in the forest

Changed in version 020 The default value of nestimators will change from 10 in version 020 to 100 in version 022

criterion string optional default”gini” The function to measure the quality of a split Sup ported criteria are “gini” for the Gini impurity and “entropy” for the information gain Note this parameter is treespecific

maxdepth integer or None optional defaultNone The maximum depth of the tree If None then nodes are expanded until all leaves are pure or until all leaves contain less than 33 Model selection and evaluation 501

scikitlearn user guide Release 0213

minsamplesplit samples

minsamplesplit int float optional default2 The minimum number of samples required to split an internal node

- If int then consider minsamplesplit as the minimum number
- If float then minsamplesplit is a fraction and ceilminsamplesplit

nsamples are the minimum number of samples for each split

Changed in version 018 Added float values for fractions

minsamplesleaf int float optional default1 The minimum number of samples required to be at a leaf node A split point at any depth will only be considered if it leaves at least minsamplesleaf training samples in each of the left and right branches This may have the effect of smoothing the model especially in regression

- If int then consider minsamplesleaf as the minimum number
- If float then minsamplesleaf is a fraction and ceilminsamplesleaf

nsamples are the minimum number of samples for each node

Changed in version 018 Added float values for fractions

minweightfractionleaf float optional default0 The minimum weighted fraction of the sum total of weights of all the input samples required to be at a leaf node Samples have equal weight when sampleweight is not provided

maxfeatures int float string or None optional default"auto" The number of features to consider when looking for the best split

- If int then consider maxfeatures features at each split
- If float then maxfeatures is a fraction and intmaxfeatures

nfeatures features are considered at each split

- If "auto" then maxfeaturessqrtnfeatures
- If "sqrt" then maxfeaturessqrtnfeatures same as "auto"
- If "log2" then maxfeatureslog2nfeatures
- If None then maxfeaturesnfeatures

Note the search for a split does not stop until at least one valid partition of the node samples

is found even if it requires to effectively inspect more than maxfeatures features

maxleafnodes int or None optional defaultNone Grow trees with maxleafnodes

in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then unlimited number of leaf nodes

minimpuritydecrease float optional default0 A node will be split if this split induces a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$N_t - N \text{ impurity} - N_t R - N_t \text{ rightimpurity}$$

$$N_t L - N_t \text{ leftimpurity}$$

where N is the total number of samples N_t is the number of samples at the current node

$N_t L$ is the number of samples in the left child and $N_t R$ is the number of samples in

the right child

$N N_t N_t R$ and $N_t L$ all refer to the weighted sum if sampleweight is passed

scikitlearn user guide Release 0213

New in version 019

minimpuritysplit float default1e7 Threshold for early stopping in tree growth A node will split if its impurity is above the threshold otherwise it is a leaf

Deprecated since version 019 minimpuritysplit has been deprecated in favor of minimpuritydecrease in 019 The default value of minimpuritysplit will change from 1e7 to 0 in 023 and it will be removed in 025 Use minimpuritydecrease instead

bootstrap boolean optional defaultTrue Whether bootstrap samples are used when building trees If False the whole dataset is used to build each tree

oobscore bool defaultFalse Whether to use outofbag samples to estimate the generalization accuracy

njobs int or None optional defaultNone The number of jobs to run in parallel for both fit and predict None means 1 unless in a joblibparallelbackend context

1means using all processors See Glossary for more details

randomstate int RandomState instance or None optional defaultNone If int randomstate is the seed used by the random number generator If RandomState instance randomstate is the random number generator If None the random number generator is the RandomState instance used by nprandom

verbose int optional default0 Controls the verbosity when fitting and predicting

warmstart bool optional defaultFalse When set to True reuse the solution of the previous call to fit and add more estimators to the ensemble otherwise just fit a whole new forest See the Glossary

classweight dict list of dicts “balanced” “balancedsubsample” or None optional defaultNone Weights associated with classes in the form classlabel weight

If not given all classes are supposed to have weight one For multioutput problems a list of dicts can be provided in the same order as the columns of y

Note that for multioutput including multilabel weights should be defined for each class of every column in its own dict For example for fourclass multilabel classification weights should be 0 1 1 1 0 1 1 5 0 1 1 1 0 1 1 1 instead of 11 25

31 41

The “balanced” mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as nsamples nclasses np

bincounty

The “balancedsubsample” mode is the same as “balanced” except that weights are computed based on the bootstrap sample for every tree grown

For multioutput the weights of each column of y will be multiplied

Note that these weights will be multiplied with sampleweight passed through the fit method if sampleweight is specified

Attributes

estimators list of DecisionTreeClassifier The collection of fitted subestimators

classes array of shape nclasses or a list of such arrays The classes labels single output problem or a list of arrays of class labels multioutput problem

nclasses int or list The number of classes single output problem or a list containing the number of classes for each output multioutput problem

33 Model selection and evaluation 503

scikitlearn user guide Release 0213

nfeatures int The number of features when fit is performed

noutputs int The number of outputs when fit is performed

featureimportances array of shape nfeatures Return the feature importances
the higher the more important the feature

oobscore float Score of the training dataset obtained using an outofbag estimate

oobdecisionfunction array of shape nsamples nclasses Decision function computed with outofbag estimate on the training set If nestimators is small it might be possible that a data point was never left out during the bootstrap In this case oobdecisionfunction might contain NaN

See also

DecisionTreeClassifier ExtraTreesClassifier

Notes

The default values for the parameters controlling the size of the trees eg maxdepth minsamplesleaf etc lead to fully grown and unpruned trees which can potentially be very large on some data sets To reduce memory consumption the complexity and size of the trees should be controlled by setting those parameter values

The features are always randomly permuted at each split Therefore the best found split may vary even with the same training data maxfeaturesnfeatures andbootstrapFalse if the improvement of the criterion is identical for several splits enumerated during the search of the best split To obtain a deterministic behaviour during fitting randomstate has to be fixed

applyselfX
Apply trees in the forest to X return leaf indices

Parameters
Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns
Xleaves arraylike shape nsamples nestimators For each datapoint x in X and for each tree in the forest return the index of the leaf x ends up in
decisionpath selfX
Return the decision path in the forest

New in version 018
Parameters
Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns
indicator sparse csr array shape nsamples nnodes Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes
nnodesptr array of size nestimators 1 The columns from indicator
tor nnodesptr in nnodesptr i 1 gives the indicator value for the ith estimator
featureimportances
Return the feature importances the higher the more important the feature
Returns

scikitlearn user guide Release 0213

featureimportances array shape nfeatures The values of this array sum to 1 unless all trees are single node trees consisting of only the root node in which case it will be an array of zeros

fitselfXysampleweightNone

Build a forest of trees from the training set X y

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The training input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse cscmatrix

yarraylike shape nsamples or nsamples noutputs The target values class labels in classification real numbers in regression

sampleweight arraylike shape nsamples or None Sample weights If None then samples are equally weighted Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node In the case of classification splits are also ignored if they would result in any single class carrying a negative weight in either child node

Returns

self object

getparams selfdeepTrue

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

predictselfX

Predict class for X

The predicted class of an input sample is a vote by the trees in the forest weighted by their probability estimates That is the predicted class is the one with highest mean probability estimate across the trees

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

yarray of shape nsamples or nsamples noutputs The predicted classes

predictlogproba selfX

Predict class logprobabilities for X

The predicted class logprobabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest

Parameters

506 Chapter 3 User Guide

scikitlearn user guide Release 0213

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

array of shape nsamples nclasses or a list of noutputs such arrays if noutputs

1 The class probabilities of the input samples The order of the classes corresponds to that in the attribute classes

predict_proba selfX

Predict class probabilities for X

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest The class probability of a single tree is the fraction of samples of the same class in a leaf

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

array of shape nsamples nclasses or a list of noutputs such arrays if noutputs

1 The class probabilities of the input samples The order of the classes corresponds to that in the attribute classes

score selfX sample_weight None

Returns the mean accuracy on the given test data and labels

In multilabel classification this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted

Parameters

Xarraylike shape nsamples nfeatures Test samples

yarraylike shape nsamples or nsamples noutputs True labels for X

sample_weight arraylike shape nsamples optional Sample weights

Returns

score float Mean accuracy of self.predictX wrt y

set_params self_params

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form component__parameter so that it's possible to update each component of a nested object

Returns

self

A random forest regressor

A random forest is a meta estimator that fits a number of classifying decision trees on various subsamples of the dataset and uses averaging to improve the predictive accuracy and control overfitting The subsample size is always the same as the original input sample size but the samples are drawn with replacement if bootstrapTrue default

Read more in the User Guide

Parameters

nestimators integer optional default10 The number of trees in the forest
Changed in version 020 The default value of nestimators will change from 10 in version 020 to 100 in version 022

criterion string optional default"mse" The function to measure the quality of a split Supported criteria are "mse" for the mean squared error which is equal to variance reduction as feature selection criterion and "mae" for the mean absolute error

New in version 018 Mean Absolute Error MAE criterion

maxdepth integer or None optional defaultNone The maximum depth of the tree If None then nodes are expanded until all leaves are pure or until all leaves contain less than minsamplessplit samples

minsamplessplit int float optional default2 The minimum number of samples required to split an internal node

- If int then consider minsamplessplit as the minimum number
- If float then minsamplessplit is a fraction and ceilminsamplessplit nsamples are the minimum number of samples for each split

Changed in version 018 Added float values for fractions

508 Chapter 3 User Guide

scikitlearn user guide Release 0213

minsamplesleaf int float optional default1 The minimum number of samples required to be at a leaf node A split point at any depth will only be considered if it leaves at least minsamplesleaf training samples in each of the left and right branches This may have the effect of smoothing the model especially in regression

- If int then consider minsamplesleaf as the minimum number
- If float then minsamplesleaf is a fraction and ceilminsamplesleaf nsamples are the minimum number of samples for each node

Changed in version 018 Added float values for fractions

minweightfractionleaf float optional default0 The minimum weighted fraction of the sum total of weights of all the input samples required to be at a leaf node Samples have equal weight when sampleweight is not provided

maxfeatures int float string or None optional default"auto" The number of features to consider when looking for the best split

- If int then consider maxfeatures features at each split
- If float then maxfeatures is a fraction and intmaxfeatures nfeatures features are considered at each split

- If "auto" then maxfeaturesnfeatures
- If "sqrt" then maxfeaturesqrtnfeatures
- If "log2" then maxfeatureslog2nfeatures
- If None then maxfeaturesnfeatures

Note the search for a split does not stop until at least one valid partition of the node samples is found even if it requires to effectively inspect more than maxfeatures features

maxleafnodes int or None optional defaultNone Grow trees with maxleafnodes in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then unlimited number of leaf nodes

minimpuritydecrease float optional default0 A node will be split if this split induces a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$N_t - N \text{ impurity} - \frac{N_t R}{N} - \frac{N_t \text{ right impurity}}{N_t L} - \frac{N_t \text{ left impurity}}{N_t L}$$

where N is the total number of samples Nt is the number of samples at the current node NtL is the number of samples in the left child and NtR is the number of samples in the right child

NNtNtR andNtL all refer to the weighted sum if sampleweight is passed

New in version 019

minimpuritysplit float default1e7 Threshold for early stopping in tree growth A node will split if its impurity is above the threshold otherwise it is a leaf

Deprecated since version 019 minimpuritysplit has been deprecated in favor of minimpuritydecrease in 019 The default value of minimpuritysplit will change from 1e7 to 0 in 023 and it will be removed in 025 Use minimpuritydecrease instead

scikitlearn user guide Release 0213

bootstrap boolean optional defaultTrue Whether bootstrap samples are used when building trees If False the whole dataset is used to build each tree

oobscore bool optional defaultFalse whether to use outofbag samples to estimate the R2 on unseen data

njobs int or None optional defaultNone The number of jobs to run in parallel for both fit and predict None means 1 unless in a joblibparallelbackend context

1means using all processors See Glossary for more details

randomstate int RandomState instance or None optional defaultNone If int ran

domstate is the seed used by the random number generator If RandomState instance

randomstate is the random number generator If None the random number generator is the RandomState instance used by nprandom

Attributes

estimators list of DecisionTreeRegressor The collection of fitted subestimators

featureimportances array of shape nfeatures Return the feature importances the higher the more important the feature

nfeatures int The number of features when fit is performed

noutputs int The number of outputs when fit is performed

oobscore float Score of the training dataset obtained using an outofbag estimate

oobprediction array of shape nsamples Prediction computed with outofbag estimate on the training set

See also

DecisionTreeRegressor ExtraTreesRegressor

Notes

The default values for the parameters controlling the size of the trees eg maxdepth

minsamplesleaf etc lead to fully grown and unpruned trees which can potentially be very large on

some data sets To reduce memory consumption the complexity and size of the trees should be controlled by setting those parameter values

The features are always randomly permuted at each split Therefore the best found split may vary even with

the same training data maxfeaturesnfeatures andbootstrapFalse if the improvement of the

criterion is identical for several splits enumerated during the search of the best split To obtain a deterministic behaviour during fitting randomstate has to be fixed

The default value maxfeaturesauto usesnfeatures rather than nfeatures 3 The latter

was originally suggested in 1 whereas the former was more recently justified empirically in 2

scikitlearn user guide Release 0213

New in version 018

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns

indicator sparse csr array shape nsamples nnodes Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes

nnodes ptr array of size nestimators 1 The columns from indicator

tree nnodes ptr i gives the indicator value for the i th estimator

feature importances

Return the feature importances the higher the more important the feature

Returns

feature importances array shape nfeatures The values of this array sum to 1 unless all trees are single node trees consisting of only the root node in which case it will be an array of zeros

fit self X y sample weight None

Build a forest of trees from the training set X y

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The training input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csc matrix

y arraylike shape nsamples or nsamples noutputs The target values class labels in classification real numbers in regression

sample weight arraylike shape nsamples or None Sample weights If None then

samples are equally weighted Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node In the case of classification splits are also ignored if they would result in any single class carrying a negative

weight in either child node

Returns

self object

get params self deep True

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

predict self X

Predict regression target for X

512 Chapter 3 User Guide

scikitlearn user guide Release 0213

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest

Parameters

Xarraylike or sparse matrix of shape (nsamples, nfeatures) The input samples Internally its dtype will be converted to dtype np.float32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns

array of shape (nsamples, noutputs) The predicted values

score self.X sample_weight None

Returns the coefficient of determination R² of the prediction

The coefficient R² is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

$2sum$ and v is the total sum of squares $y_{true} - y_{truemean}$ $2sum$ The best possible score

is 1.0 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R² score of 0.0

Parameters

Xarraylike shape (nsamples, nfeatures) Test samples For some estimators this may

be a precomputed kernel matrix instead shape (nsamples, nsamplesfitted) where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape (nsamples, noutputs) True values for X

sample_weight arraylike shape (nsamples, optional) Sample weights

Returns

score float R² of self.predict(X) wrt y

Notes

The R² score used when calling score on a regressor will use multioutputuniformaverage

from version 0.23 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

setparams self.params

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have

parameters of the form component.parameter so that it's possible to update each component

of a nested object

Returns

self

An extratrees classifier

This class implements a meta estimator that fits a number of randomized decision trees aka extratrees on various subsamples of the dataset and uses averaging to improve the predictive accuracy and control overfitting

Read more in the User Guide

Parameters

nestimators integer optional default10 The number of trees in the forest

Changed in version 020 The default value of nestimators will change from 10 in

version 020 to 100 in version 022

criterion string optional default"gini" The function to measure the quality of a split Sup

ported criteria are "gini" for the Gini impurity and "entropy" for the information gain

maxdepth integer or None optional defaultNone The maximum depth of the tree If

None then nodes are expanded until all leaves are pure or until all leaves contain less than

minsamplessplit samples

minsamplessplit int float optional default2 The minimum number of samples required

to split an internal node

- If int then consider minsamplessplit as the minimum number
- If float then minsamplessplit is a fraction and ceilminsamplessplit

nsamples are the minimum number of samples for each split

Changed in version 018 Added float values for fractions

minsamplesleaf int float optional default1 The minimum number of samples required

to be at a leaf node A split point at any depth will only be considered if it leaves at least

minsamplesleaf training samples in each of the left and right branches This may

have the effect of smoothing the model especially in regression

- If int then consider minsamplesleaf as the minimum number
- If float then minsamplesleaf is a fraction and ceilminsamplesleaf

nsamples are the minimum number of samples for each node

Changed in version 018 Added float values for fractions

minweightfractionleaf float optional default0 The minimum weighted fraction of the

sum total of weights of all the input samples required to be at a leaf node Samples have

equal weight when sampleweight is not provided

514 Chapter 3 User Guide

scikitlearn user guide Release 0213

maxfeatures int float string or None optional default"auto" The number of features to consider when looking for the best split

- If int then consider maxfeatures features at each split
- If float then maxfeatures is a fraction and intmaxfeatures nfeatures features are considered at each split
- If "auto" then maxfeatures \sqrt{n} features
- If "sqrt" then maxfeatures \sqrt{n} features
- If "log2" then maxfeatures $\log_2 n$ features
- If None then maxfeaturesnfeatures

Note the search for a split does not stop until at least one valid partition of the node samples

is found even if it requires to effectively inspect more than maxfeatures features

maxleafnodes int or None optional defaultNone Grow trees with maxleafnodes

in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then

unlimited number of leaf nodes

minimpuritydecrease float optional default0 A node will be split if this split induces

a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$Nt \cdot N \cdot \text{impurity} - NtR \cdot Nt \cdot \text{rightimpurity}$$

$$- NtL \cdot Nt \cdot \text{leftimpurity}$$

whereNis the total number of samples Nt is the number of samples at the current node

NtL is the number of samples in the left child and NtR is the number of samples in

the right child

NNtNtR andNtL all refer to the weighted sum if sampleweight is passed

New in version 019

minimpuritysplit float default1e7 Threshold for early stopping in tree growth A node

will split if its impurity is above the threshold otherwise it is a leaf

Deprecated since version 019 minimpuritysplit has been deprecated in favor of

minimpuritydecrease in 019 The default value of minimpuritysplit

will change from 1e7 to 0 in 023 and it will be removed in 025 Use

minimpuritydecrease instead

bootstrap boolean optional defaultFalse Whether bootstrap samples are used when build

ing trees If False the whole dataset is used to build each tree

oobscore bool optional defaultFalse Whether to use outofbag samples to estimate the

generalization accuracy

njobs int or None optional defaultNone The number of jobs to run in parallel for both

fit andpredict None means 1 unless in a joblibparallelbackend context

1means using all processors See Glossary for more details

randomstate int RandomState instance or None optional defaultNone If int ran

domstate is the seed used by the random number generator If RandomState instance

randomstate is the random number generator If None the random number generator is

the RandomState instance used by nprandom

verbose int optional default0 Controls the verbosity when fitting and predicting

33 Model selection and evaluation 515

scikitlearn user guide Release 0213

warmstart bool optional defaultFalse When set to True reuse the solution of the previous call to fit and add more estimators to the ensemble otherwise just fit a whole new forest See the Glossary

classweight dict list of dicts “balanced” “balancedsubsample” or None optional defaultNone Weights associated with classes in the form classlabel weight

If not given all classes are supposed to have weight one For multioutput problems a list of dicts can be provided in the same order as the columns of y

Note that for multioutput including multilabel weights should be defined for each class of every column in its own dict For example for fourclass multilabel classification weights should be 0 1 1 1 0 1 1 5 0 1 1 1 0 1 1 1 instead of 11 25

31 41

The “balanced” mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as nsamples nclasses np

bincounty

The “balancedsubsample” mode is the same as “balanced” except that weights are computed based on the bootstrap sample for every tree grown

For multioutput the weights of each column of y will be multiplied

Note that these weights will be multiplied with sampleweight passed through the fit method if sampleweight is specified

Attributes

estimators list of DecisionTreeClassifier The collection of fitted subestimators

classes array of shape nclasses or a list of such arrays The classes labels single output problem or a list of arrays of class labels multioutput problem

nclasses int or list The number of classes single output problem or a list containing the number of classes for each output multioutput problem

featureimportances array of shape nfeatures Return the feature importances the higher the more important the feature

nfeatures int The number of features when fit is performed

noutputs int The number of outputs when fit is performed

oobscore float Score of the training dataset obtained using an outofbag estimate

oobdecisionfunction array of shape nsamples nclasses Decision function computed with outofbag estimate on the training set If nestimators is small it might be possible that a data point was never left out during the bootstrap In this case

oobdecisionfunction might contain NaN

applyselfX

Apply trees in the forest to X return leaf indices

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype=np.float32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

Xleaves arraylike shape nsamples nestimators For each datapoint x in X and for each tree in the forest return the index of the leaf x ends up in

decisionpath selfX

Return the decision path in the forest

New in version 018

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype=np.float32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

indicator sparse csr array shape nsamples nnodes Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes

scikitlearn user guide Release 0213

nnodesptr array of size nestimators 1 The columns from indica
tornnodesptrinnodesptri1 gives the indicator value for the ith estimator
featureimportances

Return the feature importances the higher the more important the feature
Returns

featureimportances array shape nfeatures The values of this array sum to 1 unless
all trees are single node trees consisting of only the root node in which case it will be an
array of zeros

fitselfXysampleweightNone

Build a forest of trees from the training set X y

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The training input sam
ples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix
is provided it will be converted into a sparse cscmatrix

yarraylike shape nsamples or nsamples noutputs The target values class labels
in classification real numbers in regression

sampleweight arraylike shape nsamples or None Sample weights If None then
samples are equally weighted Splits that would create child nodes with net zero or neg
ative weight are ignored while searching for a split in each node In the case of classifi
cation splits are also ignored if they would result in any single class carrying a negative
weight in either child node

Returns

self object

getparams selfdeepTrue

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained
subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

predictselfX

Predict class for X

The predicted class of an input sample is a vote by the trees in the forest weighted by their probability
estimates That is the predicted class is the one with highest mean probability estimate across the trees

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Inter
nally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided
it will be converted into a sparse csrmatrix

Returns

yarray of shape nsamples or nsamples noutputs The predicted classes

518 Chapter 3 User Guide

scikitlearn user guide Release 0213

predictlogproba selfX

Predict class logprobabilities for X

The predicted class logprobabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns

array of shape nsamples nclasses or a list of noutputs such arrays if noutputs

1 The class probabilities of the input samples The order of the classes corresponds to that in the attribute classes

predictproba selfX

Predict class probabilities for X

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest The class probability of a single tree is the fraction of samples of the same class in a leaf

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csr matrix

Returns

array of shape nsamples nclasses or a list of noutputs such arrays if noutputs

1 The class probabilities of the input samples The order of the classes corresponds to that in the attribute classes

scoreselfXysampleweightNone

Returns the mean accuracy on the given test data and labels

In multilabel classification this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted

Parameters

Xarraylike shape nsamples nfeatures Test samples

yarraylike shape nsamples or nsamples noutputs True labels for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float Mean accuracy of selfpredictX wrt y

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form componentparameter so that it's possible to update each component of a nested object

Returns

self

An extratrees regressor

This class implements a meta estimator that fits a number of randomized decision trees aka extratrees on

various subsamples of the dataset and uses averaging to improve the predictive accuracy and control overfitting

Read more in the User Guide

Parameters

nestimators integer optional default10 The number of trees in the forest

Changed in version 020 The default value of nestimators will change from 10 in

version 020 to 100 in version 022

criterion string optional default"mse" The function to measure the quality of a split Sup
ported criteria are "mse" for the mean squared error which is equal to variance reduction as
feature selection criterion and "mae" for the mean absolute error

New in version 018 Mean Absolute Error MAE criterion

maxdepth integer or None optional defaultNone The maximum depth of the tree If
None then nodes are expanded until all leaves are pure or until all leaves contain less than

minsamplessplit samples

minsamplessplit int float optional default2 The minimum number of samples required
to split an internal node

- If int then consider minsamplessplit as the minimum number
- If float then minsamplessplit is a fraction and ceilminsamplessplit

nsamples are the minimum number of samples for each split

Changed in version 018 Added float values for fractions

minsamplesleaf int float optional default1 The minimum number of samples required
to be at a leaf node A split point at any depth will only be considered if it leaves at least

minsamplesleaf training samples in each of the left and right branches This may
have the effect of smoothing the model especially in regression

520 Chapter 3 User Guide

scikitlearn user guide Release 0213

- If int then consider minsamplesleaf as the minimum number
- If float then minsamplesleaf is a fraction and ceilminsamplesleaf

nsamples are the minimum number of samples for each node

Changed in version 018 Added float values for fractions

minweightfractionleaf float optional default0 The minimum weighted fraction of the sum total of weights of all the input samples required to be at a leaf node Samples have equal weight when sampleweight is not provided

maxfeatures int float string or None optional default"auto" The number of features to consider when looking for the best split

- If int then consider maxfeatures features at each split
- If float then maxfeatures is a fraction and intmaxfeatures
- nfeatures features are considered at each split
- If "auto" then maxfeaturesnfeatures
- If "sqrt" then maxfeaturessqrtnfeatures
- If "log2" then maxfeatureslog2nfeatures
- If None then maxfeaturesnfeatures

Note the search for a split does not stop until at least one valid partition of the node samples is found even if it requires to effectively inspect more than maxfeatures features

maxleafnodes int or None optional defaultNone Grow trees with maxleafnodes

in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then unlimited number of leaf nodes

minimpuritydecrease float optional default0 A node will be split if this split induces a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$N_t \cdot N \cdot \text{impurity} - N_t R \cdot N_t \text{rightimpurity}$$

$$- N_t L \cdot N_t \text{leftimpurity}$$

where N is the total number of samples Nt is the number of samples at the current node

NtL is the number of samples in the left child and NtR is the number of samples in

the right child

NNtNtR andNtL all refer to the weighted sum if sampleweight is passed

New in version 019

minimpuritysplit float default1e7 Threshold for early stopping in tree growth A node

will split if its impurity is above the threshold otherwise it is a leaf

Deprecated since version 019 minimpuritysplit has been deprecated in favor of

minimpuritydecrease in 019 The default value of minimpuritysplit

will change from 1e7 to 0 in 023 and it will be removed in 025 Use

minimpuritydecrease instead

bootstrap boolean optional defaultFalse Whether bootstrap samples are used when build

ing trees If False the whole dataset is used to build each tree

oobscore bool optional defaultFalse Whether to use outofbag samples to estimate the

R2 on unseen data

33 Model selection and evaluation 521

scikitlearn user guide Release 0213

njobs int or None optional defaultNone The number of jobs to run in parallel for both fit and predict None means 1 unless in a joblibparallelbackend context

1means using all processors See Glossary for more details

randomstate int RandomState instance or None optional defaultNone If int ran

domstate is the seed used by the random number generator If RandomState instance

randomstate is the random number generator If None the random number generator is the RandomState instance used by nprandom

verbose int optional default0 Controls the verbosity when fitting and predicting

warmstart bool optional defaultFalse When set to True reuse the solution of the pre

vious call to fit and add more estimators to the ensemble otherwise just fit a whole new

forest See the Glossary

Returns

Xleaves arraylike shape nsamples nestimators For each datapoint x in X and for each tree in the forest return the index of the leaf x ends up in

decisionpath selfX

Return the decision path in the forest

New in version 018

Parameters

Xarraylike or sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

indicator sparse csr array shape nsamples nnodes Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes

nnodesptr array of size nestimators 1 The columns from indicator

tor nnodesptr in nnodesptr i gives the indicator value for the ith estimator

featureimportances

Return the feature importances the higher the more important the feature

Returns

featureimportances array shape nfeatures The values of this array sum to 1 unless all trees are single node trees consisting of only the root node in which case it will be an array of zeros

fitselfXysampleweightNone

Build a forest of trees from the training set X y

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The training input samples Internally its dtype will be converted to dtype npfloat32 If a sparse matrix is provided it will be converted into a sparse cscmatrix

scikitlearn user guide Release 0213

yarraylike shape nsamples or nsamples noutputs The target values class labels in classification real numbers in regression

sampleweight arraylike shape nsamples or None Sample weights If None then samples are equally weighted Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node In the case of classification splits are also ignored if they would result in any single class carrying a negative weight in either child node

Returns

self object

getparams selfdeepTrue

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained

subobjects that are estimators

Returns

params mapping of string to any Parameter names mapped to their values

predictselfX

Predict regression target for X

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest

Parameters

Xarraylike or sparse matrix of shape nsamples nfeatures The input samples Internally its dtype will be converted to dtype=np.float32 If a sparse matrix is provided it will be converted into a sparse csrmatrix

Returns

yarray of shape nsamples or nsamples noutputs The predicted values

scoreselfXysampleweightNone

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

$2sum$ and v is the total sum of squares $y_{true} - y_{truemean}$ $2sum$ The best possible score

is 1.0 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 0.0

Parameters

Xarraylike shape nsamples nfeatures Test samples For some estimators this may be a precomputed kernel matrix instead shape nsamples nsamplesfitted where

nsamplesfitted is the number of samples used in the fitting for the estimator

yarraylike shape nsamples or nsamples noutputs True values for X

sampleweight arraylike shape nsamples optional Sample weights

Returns

score float R2 of selfpredictX wrt y

524 Chapter 3 User Guide

scikitlearn user guide Release 0213

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage from version 023 to keep consistent with metricsr2score This will influence the score method of all the multioutput regressors except for multioutputMultiOutputRegressor To specify the default value manually and avoid the warning please either call metricsr2score directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses multioutputuniformaverage setparams selfparams

Set the parameters of this estimator The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form componentparameter so that it's possible to update each component of a nested object

Returns

self Examples using sklearnensembleExtraTreesRegressor

- Face completion with a multioutput estimators
- Imputing missing values with variants of IterativeImputer

Gradient Boosting for classification

GB builds an additive model in a forward stagewise fashion it allows for the optimization of arbitrary differentiable loss functions In each stage nclasses regression trees are fit on the negative gradient of the binomial or multinomial deviance loss function Binary classification is a special case where only a single regression tree is induced

Read more in the User Guide

Parameters

33 Model selection and evaluation 525

scikitlearn user guide Release 0213

loss ‘deviance’ ‘exponential’ optional default ‘deviance’ loss function to be optimized
‘deviance’ refers to deviance logistic regression for classification with probabilistic out
puts For loss ‘exponential’ gradient boosting recovers the AdaBoost algorithm
learningrate float optional default 0.1 learning rate shrinks the contribution of each tree
by learningrate There is a tradeoff between learningrate and nestimators
nestimators int default 100 The number of boosting stages to perform Gradient boosting
is fairly robust to overfitting so a large number usually results in better performance
subsample float optional default 0.1 The fraction of samples to be used for fitting the in
dividual base learners If smaller than 10 this results in Stochastic Gradient Boosting
subsample interacts with the parameter nestimators Choosing subsample
0.1 leads to a reduction of variance and an increase in bias
criterion string optional default “friedmanmse” The function to measure the quality of
a split Supported criteria are “friedmanmse” for the mean squared error with improve
ment score by Friedman “mse” for mean squared error and “mae” for the mean absolute
error The default value of “friedmanmse” is generally the best as it can provide a better
approximation in some cases

New in version 0.18

min_samples_split int float optional default 2 The minimum number of samples required
to split an internal node

- If int then consider min_samples_split as the minimum number
- If float then min_samples_split is a fraction and ceil(min_samples_split
n_samples) are the minimum number of samples for each split

Changed in version 0.18 Added float values for fractions

min_samples_leaf int float optional default 1 The minimum number of samples required
to be at a leaf node A split point at any depth will only be considered if it leaves at least
min_samples_leaf training samples in each of the left and right branches This may
have the effect of smoothing the model especially in regression

- If int then consider min_samples_leaf as the minimum number
- If float then min_samples_leaf is a fraction and ceil(min_samples_leaf
n_samples) are the minimum number of samples for each node

Changed in version 0.18 Added float values for fractions

min_weight_fraction_leaf float optional default 0 The minimum weighted fraction of the
sum total of weights of all the input samples required to be at a leaf node Samples have
equal weight when sample_weight is not provided

max_depth integer optional default 3 maximum depth of the individual regression estima
tors The maximum depth limits the number of nodes in the tree Tune this parameter for
best performance the best value depends on the interaction of the input variables

min_impurity_decrease float optional default 0 A node will be split if this split induces
a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$N_t \cdot N \cdot \text{impurity} - N_t R \cdot N_t \cdot \text{rightimpurity}$$

$$N_t L \cdot N_t \cdot \text{leftimpurity}$$

526 Chapter 3 User Guide

scikitlearn user guide Release 0213

where N is the total number of samples N_t is the number of samples at the current node
 N_{tL} is the number of samples in the left child and N_{tR} is the number of samples in the right child
 NN_tN_{tR} and N_{tL} all refer to the weighted sum if sampleweight is passed
New in version 019
minimpuritysplit float default $1e7$ Threshold for early stopping in tree growth A node will split if its impurity is above the threshold otherwise it is a leaf
Deprecated since version 019 minimpuritysplit has been deprecated in favor of minimpuritydecrease in 019 The default value of minimpuritysplit will change from $1e7$ to 0 in 023 and it will be removed in 025 Use minimpuritydecrease instead
init estimator or 'zero' optional default None An estimator object that is used to compute the initial predictions init has to provide fit and predict_proba If 'zero' the initial raw predictions are set to zero By default a DummyEstimator predicting the classes priors is used
randomstate int RandomState instance or None optional default None If int randomstate is the seed used by the random number generator If RandomState instance randomstate is the random number generator If None the random number generator is the RandomState instance used by np.random
maxfeatures int float string or None optional default None The number of features to consider when looking for the best split
• If int then consider maxfeatures features at each split
• If float then maxfeatures is a fraction and intmaxfeatures nfeatures features are considered at each split
• If "auto" then maxfeatures = sqrt(nfeatures)
• If "sqrt" then maxfeatures = sqrt(nfeatures)
• If "log2" then maxfeatures = log2(nfeatures)
• If None then maxfeatures = nfeatures
Choosing maxfeatures nfeatures leads to a reduction of variance and an increase in bias
Note the search for a split does not stop until at least one valid partition of the node samples is found even if it requires to effectively inspect more than maxfeatures features
verbose int default 0 Enable verbose output If 1 then it prints progress and performance once in a while the more trees the lower the frequency If greater than 1 then it prints progress and performance for every tree
maxleafnodes int or None optional default None Grow trees with maxleafnodes in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then unlimited number of leaf nodes
warmstart bool default False When set to True reuse the solution of the previous call to fit and add more estimators to the ensemble otherwise just erase the previous solution See the Glossary
presort bool or 'auto' optional default 'auto' Whether to presort the data to speed up the finding of best splits in fitting Auto mode by default will use presorting on dense data and

scikitlearn user guide Release 0213

default to normal sorting on sparse data Setting presort to true on sparse data will raise an error

New in version 017 presort parameter

validationfraction float optional default 0.1 The proportion of training data to set aside as validation set for early stopping Must be between 0 and 1 Only used if niternochange is set to an integer

New in version 020

niternochange int default None niternochange is used to decide if early stopping will be used to terminate training when validation score is not improving By default it is set to None to disable early stopping If set to a number it will set aside validationfraction size of the training data as validation and terminate training when validation score is not improving in all of the previous niternochange numbers of iterations The split is stratified

New in version 020

tolfloat optional default 1e4 Tolerance for the early stopping When the loss is not improving by at least tol for niternochange iterations if set to a number the training stops

New in version 020

Attributes

nestimators int The number of estimators as selected by early stopping if niternochange is specified Otherwise it is set to nestimators

New in version 020

featureimportances array shape nfeatures Return the feature importances the higher the more important the feature

oobimprovement array shape nestimators The improvement in loss deviance on the outofbag samples relative to the previous iteration oobimprovement0 is the improvement in loss of the first stage over the init estimator

trainscore array shape nestimators The ith score trainscorei is the deviance loss of the model at iteration i on the inbag sample If subsample 1 this is the deviance on the training data

loss LossFunction The concrete LossFunction object

init_estimator The estimator that provides the initial predictions Set via the init_argument or lossinit_estimator

estimators ndarray of DecisionTreeRegressor shape nestimators lossK The collection of fitted subestimators lossK is 1 for binary classification otherwise nclasses

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Inter

nally it will be converted to dtype npfloat32 and if a sparse matrix is provided to

a sparsecsrmatrix

Returns

score array shape nsamples nclasses or nsamples The decision function of the in

put samples which corresponds to the raw values predicted from the trees of the ensemble

The order of the classes corresponds to that in the attribute classes Regression and

binary classification produce an array of shape nsamples

featureimportances

Return the feature importances the higher the more important the feature

Returns

featureimportances array shape nfeatures The values of this array sum to 1 unless

all trees are single node trees consisting of only the root node in which case it will be an

array of zeros

fitselfXysampleweightNone monitorNone

Fit the gradient boosting model

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Inter

nally it will be converted to dtype npfloat32 and if a sparse matrix is provided to

a sparsecsrmatrix

yarraylike shape nsamples Target values strings or integers in classification real

numbers in regression For classification labels must correspond to classes

sampleweight arraylike shape nsamples or None Sample weights If None then

samples are equally weighted Splits that would create child nodes with net zero or neg

ative weight are ignored while searching for a split in each node In the case of classifi

cation splits are also ignored if they would result in any single class carrying a negative

weight in either child node

monitor callable optional The monitor is called after each iteration with the current iter

ation a reference to the estimator and the local variables of fitstages as keyword

arguments callable self locals If the callable returns True the fit

ting procedure is stopped The monitor can be used for various things such as computing

heldout estimates early stopping model introspect and snapshoting

Returns

self object

getparams selfdeepTrue

Get parameters for this estimator

Parameters

deep boolean optional If True will return the parameters for this estimator and contained

subobjects that are estimators

530 Chapter 3 User Guide

scikitlearn user guide Release 0213

Returns

params mapping of string to any Parameter names mapped to their values

predictselfX

Predict class for X

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsr matrix

Returns

yarray shape nsamples The predicted values

predictlogproba selfX

Predict class logprobabilities for X

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsr matrix

Returns

parray shape nsamples nclasses The class logprobabilities of the input samples The order of the classes corresponds to that in the attribute classes

Raises

AttributeError If the loss does not support probabilities

predictproba selfX

Predict class probabilities for X

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsr matrix

Returns

parray shape nsamples nclasses The class probabilities of the input samples The order of the classes corresponds to that in the attribute classes

Raises

AttributeError If the loss does not support probabilities

scoreselfXysampleweightNone

Returns the mean accuracy on the given test data and labels

In multilabel classification this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted

Parameters

Xarraylike shape nsamples nfeatures Test samples

yarraylike shape nsamples or nsamples noutputs True labels for X

sampleweight arraylike shape nsamples optional Sample weights

33 Model selection and evaluation 531

scikitlearn user guide Release 0213

Returns

score float Mean accuracy of selfpredictX wrt y

setparams selfparams

Set the parameters of this estimator

The method works on simple estimators as well as on nested objects such as pipelines The latter have parameters of the form componentparameter so that it's possible to update each component of a nested object

Returns

self

stageddecisionfunction selfX

Compute decision function of Xfor each iteration

This method allows monitoring ie determine error on testing set after each stage

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsrmatrix

Returns

score generator of array shape nsamples k The decision function of the input samples which corresponds to the raw values predicted from the trees of the ensemble The classes corresponds to that in the attribute classes Regression and binary classification are special cases with k 1 otherwise knclasses

stagedpredict selfX

Predict class at each stage for X

This method allows monitoring ie determine error on testing set after each stage

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsrmatrix

Returns

ygenerator of array of shape nsamples The predicted value of the input samples

stagedpredictproba selfX

Predict class probabilities at each stage for X

This method allows monitoring ie determine error on testing set after each stage

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtype npfloat32 and if a sparse matrix is provided to a sparsecsrmatrix

Returns

ygenerator of array of shape nsamples The predicted value of the input samples

Gradient Boosting for regression

GB builds an additive model in a forward stagewise fashion it allows for the optimization of arbitrary differentiable loss functions In each stage a regression tree is fit on the negative gradient of the given loss function

Read more in the User Guide

Parameters

loss 'ls' 'lad' 'huber' 'quantile' optional default'ls' loss function to be optimized 'ls'

refers to least squares regression 'lad' least absolute deviation is a highly robust loss function solely based on order information of the input variables 'huber' is a combination of the two 'quantile' allows quantile regression use alpha to specify the quantile learningrate float optional default01 learning rate shrinks the contribution of each tree bylearningrate There is a tradeoff between learningrate and nestimators

nestimators int default100 The number of boosting stages to perform Gradient boosting is fairly robust to overfitting so a large number usually results in better performance subsample float optional default10 The fraction of samples to be used for fitting the individual base learners If smaller than 10 this results in Stochastic Gradient Boosting subsample interacts with the parameter nestimators Choosing subsample 10 leads to a reduction of variance and an increase in bias

criterion string optional default"friedmanmse" The function to measure the quality of a split Supported criteria are "friedmanmse" for the mean squared error with improvement score by Friedman "mse" for mean squared error and "mae" for the mean absolute error The default value of "friedmanmse" is generally the best as it can provide a better approximation in some cases

33 Model selection and evaluation 533

scikitlearn user guide Release 0213

New in version 018

minsamplessplit int float optional default2 The minimum number of samples required to split an internal node

- If int then consider minsamplessplit as the minimum number
- If float then minsamplessplit is a fraction and ceilminsamplessplit

nsamples are the minimum number of samples for each split

Changed in version 018 Added float values for fractions

minsamplesleaf int float optional default1 The minimum number of samples required to be at a leaf node A split point at any depth will only be considered if it leaves at least minsamplesleaf training samples in each of the left and right branches This may have the effect of smoothing the model especially in regression

- If int then consider minsamplesleaf as the minimum number
- If float then minsamplesleaf is a fraction and ceilminsamplesleaf

nsamples are the minimum number of samples for each node

Changed in version 018 Added float values for fractions

minweightfractionleaf float optional default0 The minimum weighted fraction of the sum total of weights of all the input samples required to be at a leaf node Samples have equal weight when sampleweight is not provided

maxdepth integer optional default3 maximum depth of the individual regression estimators The maximum depth limits the number of nodes in the tree Tune this parameter for best performance the best value depends on the interaction of the input variables

minimpuritydecrease float optional default0 A node will be split if this split induces a decrease of the impurity greater than or equal to this value

The weighted impurity decrease equation is the following

$$N_t \cdot N \cdot \text{impurity} - N_t R \cdot N_t \cdot \text{rightimpurity}$$

$$- N_t L \cdot N_t \cdot \text{leftimpurity}$$

where N is the total number of samples N_t is the number of samples at the current node

$N_t L$ is the number of samples in the left child and $N_t R$ is the number of samples in the right child

N , $N_t R$ and $N_t L$ all refer to the weighted sum if sampleweight is passed

New in version 019

minimpuritysplit float default1e7 Threshold for early stopping in tree growth A node will split if its impurity is above the threshold otherwise it is a leaf

Deprecated since version 019 minimpuritysplit has been deprecated in favor of

minimpuritydecrease in 019 The default value of minimpuritysplit will change from 1e7 to 0 in 023 and it will be removed in 025 Use

minimpuritydecrease instead

init estimator or 'zero' optional defaultNone An estimator object that is used to compute the initial predictions init has to provide fit and predict If 'zero' the initial raw predictions are set to zero By default a DummyEstimator is used predicting either the average target value for loss'ls' or a quantile for the other losses

randomstate int RandomState instance or None optional defaultNone If int randomstate is the seed used by the random number generator If RandomState instance

scikitlearn user guide Release 0213

randomstate is the random number generator If None the random number generator is the RandomState instance used by nprandom

maxfeatures int float string or None optional defaultNone The number of features to consider when looking for the best split

- If int then consider maxfeatures features at each split
- If float then maxfeatures is a fraction and intmaxfeatures nfeatures features are considered at each split
- If “auto” then maxfeaturesnfeatures
- If “sqrt” then maxfeaturesqrtnfeatures
- If “log2” then maxfeatureslog2nfeatures
- If None then maxfeaturesnfeatures

Choosingmaxfeatures nfeatures leads to a reduction of variance and an increase in bias

Note the search for a split does not stop until at least one valid partition of the node samples is found even if it requires to effectively inspect more than maxfeatures features

alpha float default0.9 The alphaquantile of the huber loss function and the quantile loss function Only if loss=huber or loss=quantile

verbose int default 0 Enable verbose output If 1 then it prints progress and performance once in a while the more trees the lower the frequency If greater than 1 then it prints progress and performance for every tree

maxleaffnodes int or None optional defaultNone Grow trees with maxleaffnodes in bestfirst fashion Best nodes are defined as relative reduction in impurity If None then unlimited number of leaf nodes

warmstart bool default False When set to True reuse the solution of the previous call to fit and add more estimators to the ensemble otherwise just erase the previous solution See the Glossary

presort bool or ‘auto’ optional default‘auto’ Whether to presort the data to speed up the finding of best splits in fitting Auto mode by default will use presorting on dense data and default to normal sorting on sparse data Setting presort to true on sparse data will raise an error

New in version 0.17 optional parameter presort

validationfraction float optional default 0.1 The proportion of training data to set aside as validation set for early stopping Must be between 0 and 1 Only used if niternochange is set to an integer

New in version 0.20

niternochange int default None niternochange is used to decide if early stopping will be used to terminate training when validation score is not improving By default it is set to None to disable early stopping If set to a number it will set aside validationfraction size of the training data as validation and terminate training when validation score is not improving in all of the previous niternochange numbers of iterations

New in version 0.20

33 Model selection and evaluation 535

scikitlearn user guide Release 0213

tolfloat optional default 1e4 Tolerance for the early stopping When the loss is not improv
ing by at least tol for niternochange iterations if set to a number the training
stops

New in version 020

Attributes

applyselfX

Apply trees in the ensemble to X return leaf indices

New in version 017

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally its dtype will be converted to dtypepenfloat32 If a sparse matrix is provided it will be converted to a sparse csrmatrix

Returns

Xleaves arraylike shape nsamples nestimators For each datapoint x in X and for each tree in the ensemble return the index of the leaf x ends up in each estimator

featureimportances

Return the feature importances the higher the more important the feature

Returns

featureimportances array shape nfeatures The values of this array sum to 1 unless all trees are single node trees consisting of only the root node in which case it will be an array of zeros

fitselfXysampleweightNone monitorNone

Fit the gradient boosting model

Parameters

Xarraylike sparse matrix shape nsamples nfeatures The input samples Internally it will be converted to dtypepenfloat32 and if a sparse matrix is provided to a sparsecsrmatrix

yarraylike shape nsamples Target values strings or integers in classification real

numbers in regression For classification labels must correspond to classes

sampleweight arraylike shape nsamples or None Sample weights If None then

samples are equally weighted Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node In the case of classification splits are also ignored if they would result in any single class carrying a negative weight in either child node

monitor callable optional The monitor is called after each iteration with the current iteration a reference to the estimator and the local variables of fitstages as keyword

scikitlearn user guide Release 0213

argumentscallable: self locals If the callable returns True the fitting procedure is stopped The monitor can be used for various things such as computing heldout estimates early stopping model introspect and snapshoting

Returns

self object

getparams selfdeep: True

Get parameters for this estimator

Parameters

deep: boolean optional If True will return the parameters for this estimator and contained subobjects that are estimators

Returns

params: mapping of string to any Parameter names mapped to their values

predictselfX

Predict regression target for X

Parameters

X: arraylike sparse matrix shape (nsamples, nfeatures) The input samples Internally it will be converted to dtype np.float32 and if a sparse matrix is provided to a sparse matrix

Returns

y: array shape (nsamples,) The predicted values

scoreselfX: sampleweight: None

Returns the coefficient of determination R2 of the prediction

The coefficient R2 is defined as $1 - \frac{u}{v}$ where u is the residual sum of squares $y_{true} - y_{pred}$

\sum^2 and v is the total sum of squares $y_{true} - y_{true\text{mean}}$ \sum^2 The best possible score

is 1.0 and it can be negative because the model can be arbitrarily worse A constant model that always

predicts the expected value of y disregarding the input features would get a R2 score of 0.0

Parameters

X: arraylike shape (nsamples, nfeatures) Test samples For some estimators this may

be a precomputed kernel matrix instead shape (nsamples, nsamplesfitted) where

nsamplesfitted is the number of samples used in the fitting for the estimator

y: arraylike shape (nsamples,) or (nsamples, noutputs) True values for X

sampleweight: arraylike shape (nsamples,) optional Sample weights

Returns

score: float R2 of self.predictX wrt y

Notes

The R2 score used when calling score on a regressor will use multioutputuniformaverage

from version 0.23 to keep consistent with metricsr2score This will influence the score

method of all the multioutput regressors except for multioutputMultiOutputRegressor

To specify the default value manually and avoid the warning please either call metricsr2score

directly or make a custom scorer with metricsmakescorer the builtin scorer r2 uses

multioutputuniformaverage

- Partial Dependence Plots

333 Model evaluation quantifying the quality of predictions

There are 3 different APIs for evaluating the quality of a model's predictions

•Estimator score method Estimators have a score method providing a default evaluation criterion for the problem they are designed to solve This is not discussed on this page but in each estimator's documentation

•Scoring parameter Modevaluation tools using crossvalidation such asmodelselection crossvalscore andmodelselectionGridSearchCV rely on an internal scoring strategy This

is discussed in the section The scoring parameter defining model evaluation rules

•Metric functions Themetrics module implements functions assessing prediction error for specific purposes These metrics are detailed in sections on Classification metrics Multilabel ranking metrics Regression metrics andClustering metrics

Finally Dummy estimators are useful to get a baseline value of those metrics for random predictions

See also

For "pairwise" metrics between samples and not estimators or predictions see the Pairwise metrics Affinities and Kernels section

33 Model selection and evaluation 539

The scoring parameter defining model evaluation rules

Model selection and evaluation using tools such as `modelselectionGridSearchCV` and

`modelselectioncrossvalscore` take as scoring parameter that controls what metric they ap

ply to the estimators evaluated

Common cases predefined values

For the most common use cases you can designate a scorer object with the scoring parameter the table below

shows all possible values All scorer objects follow the convention that higher return values are better than

lower return values Thus metrics which measure the distance between the model and the data like metrics

`meansquarederror` are available as `negmeansquarederror` which return the negated value of the metric

Scoring Function Comment

Classification

ValueError wrongchoice is not a valid scoring value Use sortedsklearnmetrics

→SCORERSkeys to get valid options

Note The values listed by the ValueError exception correspond to the functions measuring prediction accuracy described in the following sections The scorer objects for those functions are stored in the dictionary sklearn metricsSCORERS

Defining your scoring strategy from metric functions

The module sklearnmetrics also exposes a set of simple functions measuring a prediction error given ground truth and prediction

- functions ending with score return a value to maximize the higher the better
- functions ending with error orloss return a value to minimize the lower the better When converting into a scorer object using makescorer set thegreaterisbetter parameter to False True by default see the parameter description below

Metrics available for various machine learning tasks are detailed in sections below

Many metrics are not given names to be used as scoring values sometimes because they require additional parameters such as fbeta score In such cases you need to generate an appropriate scoring object The simplest way to generate a callable object for scoring is by using makescorer That function converts metrics into callables that can be used for model evaluation

One typical use case is to wrap an existing metric function from the library with nondefault values for its parameters such as the beta parameter for the fbeta score function

```
from sklearnmetrics import fbeta score makescorer
ftwoscorer makescorerfbeta score beta2
from sklearnmodelselection import GridSearchCV
from sklearnsvm import LinearSVC
grid GridSearchCVLinearSVC paramgridC 1 10
scoringftwoscorer cv5
```

The second use case is to build a completely custom scorer object from a simple python function using makescorer which can take several parameters

- the python function you want to use mycustomlossfunc in the example below
- whether the python function returns a score greaterisbetterTrue the default or a loss greaterisbetterFalse If a loss the output of the python function is negated by the scorer object conforming to the cross validation convention that scorers return higher values for better models
- for classification metrics only whether the python function you provided requires continuous decision certain ties needsthresholdTrue The default value is False
- any additional parameters such as beta orlabels inf1score

33 Model selection and evaluation 541

scikitlearn user guide Release 0213

Here is an example of building custom scorers and of using the greaterisbetter parameter

```
import numpy as np
def mycustomlossfuncytrue ypred
diff npabsytrue ypredmax
return nplog1pdiff
```

score will negate the return value of mycustomlossfunc
which will be nplog2 0693 given the values for X
and y defined below

```
score makescorermycustomlossfunc greaterisbetter False
X 1 1
y 0 1
from sklearndummy import DummyClassifier
clf DummyClassifierstrategymostfrequent randomstate0
clf clffitX y
mycustomlossfuncclfpredictX y
069
scoreclf X y
069
```

Implementing your own scoring object

You can generate even more flexible model scorers by constructing your own scoring object from scratch without using
themakescorer factory For a callable to be a scorer it needs to meet the protocol specified by the following two
rules

- It can be called with parameters estimator X y whereestimator is the model that should be
evaluatedXis validation data and yis the ground truth target for Xin the supervised case or None in the
unsupervised case
- It returns a floating point number that quantifies the estimator prediction quality on X with reference to y

Again by convention higher numbers are better so if your scorer returns loss that value should be negated

Note Using custom scorers in functions where njobs 1

While defining the custom scoring function alongside the calling function should work out of the box with the default
joblib backend loky importing it from another module will be a more robust approach and work independently of
the joblib backend

For example to use njobs greater than 1 in the example below customscoringfunction function is saved
in a usercreated module customscorermodulepy and imported

```
from customscorermodule import customscoringfunction
crossvalscoremodel
Xtrain
ytrain
scoringmakescorercustomscoringfunction greaterisbetter False
cv5
njobs1
```

scikitlearn user guide Release 0213

Using multiple metric evaluation

Scikitlearn also permits evaluation of multiple metrics in GridSearchCV RandomizedSearchCV and crossvalidate

There are two ways to specify multiple scoring metrics for the scoring parameter

- As an iterable of string metrics

scoring accuracy precision

- As a dict mapping the scorer name to the scoring function

from sklearn.metrics import accuracyscore

from sklearn.metrics import makescorer

scoring accuracy makescoreraccuracyscore

prec precision

Note that the dict values can either be scorer functions or one of the predefined metric strings

Currently only those scorer functions that return a single score can be passed inside the dict Scorer functions that

return multiple values are not permitted and will require a wrapper to return a single metric

from sklearn.model_selection import crossvalidate

from sklearn.metrics import confusionmatrix

A sample toy binary classification dataset

X y datasets.make_classification(n_classes=2, random_state=0)

svm = LinearSVC(random_state=0)

def tnytrue ypred return confusionmatrix(ytrue, ypred)[0][0]

def fpytrue ypred return confusionmatrix(ytrue, ypred)[0][1]

def fnytrue ypred return confusionmatrix(ytrue, ypred)[1][0]

def tpytrue ypred return confusionmatrix(ytrue, ypred)[1][1]

scoring = {'tp': makescorer(tp), 'tn': makescorer(tn),

'fp': makescorer(fp), 'fn': makescorer(fn)}

cv_results = cross_validate(svm_fit, X, y, scoring=scoring, cv=5)

scoring = scoring[0]

Getting the test set true positive scores

print cv_results['test_tp']

10 9 8 7 8

Getting the test set false negative scores

print cv_results['test_fn']

0 1 2 3 2

Classification metrics

The sklearn.metrics module implements several loss score and utility functions to measure classification per-

formance. Some metrics might require probability estimates of the positive class confidence values or binary deci-

sions values. Most implementations allow each sample to provide a weighted contribution to the overall score through

the sample_weight parameter.

Some of these are restricted to the binary classification case.

precision_recall_curve(ytrue, probascore) Compute precision-recall pairs for different probability

thresholds

roc_curve(ytrue, yscore, poslabel) Compute Receiver operating characteristic (ROC)

balanced_accuracy_score(ytrue, ypred) Compute the balanced accuracy

33 Model selection and evaluation 543

scikitlearn user guide Release 0213

Others also work in the multiclass case

cohenkappascore y1 y2 labels weights Cohen’s kappa a statistic that measures interannotator agreement

confusionmatrix ytrue ypred labels Compute confusion matrix to evaluate the accuracy of a classification

hinge loss ytrue preddecision labels Average hinge loss nonregularized

matthewscore ytrue ypred Compute the Matthews correlation coefficient MCC

Some also work in the multilabel case

accuracy ytrue ypred normalize Accuracy classification score

classificationreport ytrue ypred Build a text report showing the main classification metrics

f1score ytrue ypred labels Compute the F1 score also known as balanced Fscore or Fmeasure

fbetascore ytrue ypred beta labels Compute the Fbeta score

hammingloss ytrue ypred labels Compute the average Hamming loss

jaccardscore ytrue ypred labels Jaccard similarity coefficient score

logloss ytrue ypred eps normalize Log loss aka logistic loss or crossentropy loss

multilabelconfusionmatrix ytrue ypred Compute a confusion matrix for each class or sample

precisionrecallfscoresupport ytrue ypred Compute precision recall Fmeasure and support for each class

precisionscore ytrue ypred labels Compute the precision

recallscore ytrue ypred labels Compute the recall

zeroone loss ytrue ypred normalize Zeroone classification loss

And some work with binary and multilabel but not multiclass problems

averageprecisionscore ytrue yscore Compute average precision AP from prediction scores

rocaucscore ytrue yscore average Compute Area Under the Receiver Operating Characteristic Curve ROC AUC from prediction scores

In the following subsections we will describe each of those functions preceded by some notes on common API (Application Programming Interface) metric definition

From binary to multiclass and multilabel

Some metrics are essentially defined for binary classification tasks eg f1score rocaucscore In these

cases by default only the positive label is evaluated assuming by default that the positive class is labelled 1 though this may be configurable through the poslabel parameter

In extending a binary metric to multiclass or multilabel problems the data is treated as a collection of binary problems one for each class There are then a number of ways to average binary metric calculations across the set of classes each of which may be useful in some scenario Where available you should select among these using the average parameter

•macro simply calculates the mean of the binary metrics giving equal weight to each class In problems where infrequent classes are nonetheless important macroaveraging may be a means of highlighting their performance On the other hand the assumption that all classes are equally important is often untrue such that macroaveraging will overemphasize the typically low performance on an infrequent class

544 Chapter 3 User Guide

scikitlearn user guide Release 0213

- weighted accounts for class imbalance by computing the average of binary metrics in which each class’s score is weighted by its presence in the true data sample
 - micro gives each sampleclass pair an equal contribution to the overall metric except as a result of sample weight Rather than summing the metric per class this sums the dividends and divisors that make up the perclass metrics to calculate an overall quotient Microaveraging may be preferred in multilabel settings including multiclass classification where a majority class is to be ignored
 - samples applies only to multilabel problems It does not calculate a perclass measure instead calculat ing the metric over the true and predicted classes for each sample in the evaluation data and returning their sampleweight weighted average
 - Selecting averageNone will return an array with the score for each class
- While multiclass data is provided to the metric like binary targets as an array of class labels multilabel data is specified as an indicator matrix in which cell i j has value 1 if sample ihas labeljand value 0 otherwise

Accuracy score

Theaccuracyscore function computes the accuracy either the fraction default or the count normalizeFalse of correct predictions

In multilabel classification the function returns the subset accuracy If the entire set of predicted labels for a sample strictly match with the true set of labels then the subset accuracy is 10 otherwise it is 00

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the fraction of correct predictions over n samples is defined as

$$\text{accuracy} = \frac{1}{n} \sum_{i=1}^n \mathbb{1}_{\hat{y}_i = y_i}$$

where $\mathbb{1}$ is the indicator function

```
import numpy as np
from sklearn.metrics import accuracy_score

ypred = [0, 2, 1, 3]
ytrue = [0, 1, 2, 3]
accuracy_score(ytrue, ypred)
0.5
accuracy_score(ytrue, ypred, normalize=False)
2
```

In the multilabel case with binary label indicators

```
accuracy_score(np.array([0, 1, 1, 1]), np.ones(2, 2))
0.5
```

- Example
- See Test with permutations the significance of a classification score for an example of accuracy score usage using permutations of the dataset
- 33 Model selection and evaluation 545

Balanced accuracy score

The `balancedaccruracyscore` function computes the balanced accuracy which avoids inflated performance estimates on imbalanced datasets It is the macroaverage of recall scores per class or equivalently raw accuracy where each sample is weighted according to the inverse prevalence of its true class Thus for balanced datasets the score is equal to accuracy

In the binary case balanced accuracy is equal to the arithmetic mean of sensitivity true positive rate and specificity true negative rate or the area under the ROC curve with binary predictions rather than scores

If the classifier performs equally well on either class this term reduces to the conventional accuracy ie the number of correct predictions divided by the total number of predictions

In contrast if the conventional accuracy is above chance only because the classifier takes advantage of an imbalanced test set then the balanced accuracy as appropriate will drop to 1

0000000000

The score ranges from 0 to 1 or when adjustedTrue is used it rescaled to the range 1

1-0000000000 to 1 inclusive

with performance at random scoring 0

If y_i is the true value of the i th sample and \hat{y}_i is the corresponding sample weight then we adjust the sample weight to

0000000000

$\hat{y}_i = 1 - y_i$

where 1_{ij} is the indicator function Given predicted \hat{y}_i for sample i balanced accuracy is defined as

balanced accuracy $\hat{y}_i = 1 - \sum_{j=1}^n \hat{y}_{ij}$

00000000 00

With `adjustedTrue` balanced accuracy reports the relative increase from balanced accuracy $\hat{y}_i = 0$

1

0000000000 In the binary case this is also known as Youden’s J statistic or informedness

Note The multiclass definition here seems the most reasonable extension of the metric used in binary classification though there is no certain consensus in the literature

- Our definition Mosley2013 Kelleher2015 and Guyon2015 where Guyon2015 adopt the adjusted version to ensure that random predictions have a score of 0 and perfect predictions have a score of 1
- Class balanced accuracy as described in Mosley2013 the minimum between the precision and the recall for each class is computed Those values are then averaged over the total number of classes to get the balanced accuracy
- Balanced Accuracy as described in Urbanowicz2015 the average of sensitivity and specificity is computed for each class and then averaged over total number of classes

References

Cohen’s kappa

The function `cohenkappascore` computes Cohen’s kappa statistic This measure is intended to compare label ings by different human annotators not a classifier versus a ground truth

The kappa score see `docstring` is a number between -1 and 1 Scores above 0.8 are generally considered good agreement zero or lower means no agreement practically random labels

scikitlearn user guide Release 0213

Kappa scores can be computed for binary or multiclass problems but not for multilabel problems except by manually computing a perlabel score and not for more than two annotators

```
from sklearn.metrics import cohenkappascore
```

```
ytrue 2 0 2 2 0 1
```

```
ypred 0 0 2 2 0 2
```

```
cohenkappascore(ytrue, ypred)
```

```
0.4285714285714286
```

Confusion matrix

The confusion matrix function evaluates classification accuracy by computing the confusion matrix with each row corresponding to the true class https://en.wikipedia.org/wiki/Confusion_matrix. Wikipedia and other references may use different convention for axes

By definition entry C_{ij} in a confusion matrix is the number of observations actually in group j but predicted to be in group i . Here is an example

```
from sklearn.metrics import confusion_matrix
```

```
ytrue 2 0 2 2 0 1
```

```
ypred 0 0 2 2 0 2
```

```
confusion_matrix(ytrue, ypred)
```

```
array([[2, 0, 0]
```

```
       [0, 0, 1]
```

```
       [1, 0, 2]])
```

Here is a visual representation of such a confusion matrix this figure comes from the Confusion matrix example

For binary problems we can

get counts of true negatives false positives false negatives and true positives as follows

```
ytrue 0 0 0 1 1 1 1 1
```

```
ypred 0 1 0 1 0 1 0 1
```

```
tn fp fn tp confusion_matrix(ytrue, ypred).ravel()
```

```
33 Model selection and evaluation 547
```

tn fp fn tp

2 1 2 3

Example

- See Confusion matrix for an example of using a confusion matrix to evaluate classifier output quality
- See Recognizing handwritten digits for an example of using a confusion matrix to classify handwritten digits
- See Classification of text documents using sparse features for an example of using a confusion matrix to classify text documents

Classification report

Theclassificationreport function builds a text report showing the main classification metrics Here is a small example with custom targetnames and inferred labels

```
from sklearn.metrics import classification_report
ytrue 0 1 2 2 0
ypred 0 0 2 1 0
targetnames class 0 class 1 class 2
printclassification_report(ytrue, ypred, targetnames)
precision recall f1score support
class 0 0.67 1.00 0.80 2
class 1 0.00 0.00 0.00 1
class 2 1.00 0.50 0.67 2
accuracy 0.60 5
macro avg 0.56 0.50 0.49 5
weighted avg 0.67 0.60 0.59 5
```

Example

- See Recognizing handwritten digits for an example of classification report usage for handwritten digits
- See Classification of text documents using sparse features for an example of classification report usage for text documents
- See Parameter estimation using grid search with crossvalidation for an example of classification report usage for grid search with nested crossvalidation

Hamming loss

Thehammingloss computes the average Hamming loss or Hamming distance between two sets of samples If is the predicted value for the th label of a given sample is the corresponding true value and labels is the number of classes or labels then the Hamming loss between two samples is defined as

$$\frac{1}{\text{labels}} \sum_{i=1}^{\text{labels}} \frac{|y_i - \hat{y}_i|}{\text{labels}}$$

scikitlearn user guide Release 0213

where $1_{\{i\}}$ is the indicator function

```
from sklearn.metrics import hammingloss
ypred = [1, 2, 3, 4]
ytrue = [2, 2, 3, 4]
hammingloss(ytrue, ypred)
```

0.25

In the multilabel case with binary label indicators

```
hammingloss(np.array([0, 1, 1, 1]), np.zeros(2))
```

0.75

Note In multiclass classification the Hamming loss corresponds to the Hamming distance between y_{true} and y_{pred} which is similar to the Zero one loss function. However while zeroone loss penalizes prediction sets that do not strictly match true sets the Hamming loss penalizes individual labels. Thus the Hamming loss upper bounded by the zeroone loss is always between zero and one inclusive and predicting a proper subset or superset of the true labels will give a Hamming loss between zero and one exclusive.

Precision recall and Fmeasures

Intuitively precision is the ability of the classifier not to label as positive a sample that is negative and recall is the ability of the classifier to find all the positive samples.

The Fmeasure $\frac{2pr}{p+r}$ and $\frac{2}{\frac{1}{p} + \frac{1}{r}}$ measures can be interpreted as a weighted harmonic mean of the precision and recall. A $\frac{2pr}{p+r}$ measure reaches its best value at 1 and its worst score at 0. With $\frac{1}{\frac{1}{p} + \frac{1}{r}}$ and $\frac{2pr}{p+r}$ are equivalent and the recall and the precision are equally important.

The `precisionrecallcurve` computes a precision-recall curve from the ground truth label and a score given by the classifier by varying a decision threshold.

The `averageprecisionscore` function computes the average precision AP from prediction scores. The value is between 0 and 1 and higher is better. AP is defined as

$$AP = \frac{\sum_{n=1}^N p_n - p_N}{N}$$

where p_n and p_N are the precision and recall at the n th threshold. With random predictions the AP is the fraction of positive samples.

References Manning2008 and Everingham2010 present alternative variants of AP that interpolate the precision-recall curve. Currently `averageprecisionscore` does not implement any interpolated variant. References

Davis2006 and Flach2015 describe why a linear interpolation of points on the precision-recall curve provides an overly optimistic measure of classifier performance. This linear interpolation is used when computing area under the curve with the trapezoidal rule in `auc`.

Several functions allow you to analyze the precision recall and Fmeasures score.

`averageprecisionscore(ytrue, yscore)` Compute average precision AP from prediction scores

`f1score(ytrue, ypred, labels)` Compute the F1 score also known as balanced Fscore or

Fmeasure

`fbetascore(ytrue, ypred, beta, labels)` Compute the Fbeta score

`precisionrecallcurve(ytrue, probaspred)` Compute precision-recall pairs for different probability thresholds

Continued on next page

precisionrecallfscoresupport ytrue

References

Binary classification

In a binary classification task the terms “positive” and “negative” refer to the classifier’s prediction and the terms “true” and “false” refer to whether that prediction corresponds to the external judgment sometimes known as the “observation” Given these definitions we can formulate the following table

Actual class observation

Predicted class expectation tp true positive Correct result fp false positive Unexpected result

fn false negative Missing result tn true negative Correct absence of result

In this context we can define the notions of precision recall and Fmeasure

precision $\frac{tp}{tp+fp}$

$\frac{precision}{recall}$

recall $\frac{tp}{tp+fn}$

$\frac{precision \times recall}{2 \times precision + 2 \times recall}$

$\frac{1}{\frac{1}{2 \times precision} + \frac{1}{2 \times recall}}$

$\frac{2 \times precision \times recall}{precision + recall}$

Here are some small examples in binary classification

Multiclass and multilabel classification

In multiclass and multilabel classification task the notions of precision recall and Fmeasures can be applied to each label independently There are a few ways to combine results across labels specified by the average argument to the averageprecisionscore multilabel only f1score fbetascore precisionrecallfscoresupport precisionscore andrecallscore functions as described above Note that if all labels are included “micro”averaging in a multiclass setting will produce precision recall and that are all identical to accuracy Also note that “weighted” averaging may produce an Fscore that is not between precision and recall

To make this more explicit consider the following notation

- the set of predicted pairs
 - the set of true pairs
 - the set of labels
 - the set of samples
 - the subset of with sample ie ‘ \in ’
 - the subset of with label
 - similarly and are subsets of
 - \cap
- for some sets and
- \cap

Conventions vary on handling \emptyset this implementation uses $\emptyset = 0$ and similar for

```

Hinge loss
The hinge loss function computes the average distance between the model and the data using hinge loss a one sided metric that considers only prediction errors Hinge loss is used in maximal margin classifiers such as support vector machines

If the labels are encoded with 1 and -1 y is the true value and \hat{y} is the predicted decisions as output by decision function then the hinge loss is defined as

$$L_{\text{Hinge}}(y, \hat{y}) = \max(1 - y\hat{y}, 0)$$

If there are more than two labels hinge loss uses a multiclass variant due to Crammer & Singer Here is the paper describing it

If \hat{y}_i is the predicted decision for true label and $\max_{j \neq i} \hat{y}_j$ is the maximum of the predicted decisions for all other labels where predicted decisions are output by decision function then multiclass hinge loss is defined by

$$L_{\text{Hinge}}(y, \hat{y}) = \max(1 - y\hat{y}, \max_{j \neq y} (y\hat{y}_j - \hat{y}_j))$$

Here a small example demonstrating the use of the hinge loss function with a svm classifier in a binary class problem

```
from sklearn import svm

Log loss
Log loss also called logistic regression loss or crossentropy loss is defined on probability estimates It is commonly used in multinomial logistic regression and neural networks as well as in some variants of expectationmaximization and can be used to evaluate the probability outputs predictproba of a classifier instead of its discrete predictions

For binary classification with a true label $y \in \{0,1\}$ and a probability estimate $\hat{p} = \text{Pr}[Y=1]$ the log loss per sample is the negative loglikelihood of the classifier given the true label

$$-\log \hat{p}^y - \log \text{Pr}[Y=y] = -\log \hat{p}^1 - (1-\hat{p}) \log 1 - (1-\hat{p}) \log 1 - \hat{p}$$

This extends to the multiclass case as follows Let the true labels for a set of samples be encoded as a 1ofK binary indicator matrix Y ie $Y_{ij} = 1$ if sample i has label j taken from a set of K labels Let \hat{p} be a matrix of probability estimates with $\hat{p}_{ij} = \text{Pr}[Y_{ij}=1]$ Then the log loss of the whole set is

$$-\log \hat{p}^y - \log \text{Pr}[Y=y] = -1 - \sum_{j=1}^K \hat{p}_{ij} \log \hat{p}_{ij}$$

To see how this generalizes the binary log loss given above note that in the binary case $\hat{p}_{i0} = 1 - \hat{p}_{i1}$ and $\hat{p}_{i0} \log \hat{p}_{i0} = (1 - \hat{p}_{i1}) \log (1 - \hat{p}_{i1})$ so expanding the inner sum over $\hat{p}_{ij} \in \{0,1\}$ gives the binary log loss

The logloss function computes log loss given a list of groundtruth labels and a probability matrix as returned by an estimator's predictproba method

```
from sklearn.metrics import logloss
```

```
ytrue 0 0 1 1
```

scikitlearn user guide Release 0213

ypred 9 1 8 2 3 7 0 1 99

loglossytrue ypred

01738

The first9 1 in ypred denotes 90 probability that the first sample has label 0 The log loss is nonnegative Matthews correlation coefficient

The matthewscore function computes the Matthew’s correlation coefficient MCC for binary classes

Quoting Wikipedia

“The Matthews correlation coefficient is used in machine learning as a measure of the quality of binary twoclass classifications It takes into account true and false positives and negatives and is generally regarded as a balanced measure which can be used even if the classes are of very different sizes The MCC is in essence a correlation coefficient value between 1 and 1 A coefficient of 1 represents a perfect prediction 0 an average random prediction and 1 an inverse prediction The statistic is also known as the phi coefficient”

In the binary twoclass case TP and FN are respectively the number of true positives true negatives false positives and false negatives the MCC is defined as

$$\frac{TP \times TN - FP \times FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}}$$

In the multiclass case the Matthews correlation coefficient can be defined in terms of a confusionmatrix C for

C classes To simplify the definition consider the following intermediate variables

• $\sum_i C_{ii}$

$\sum_i C_{ii}$ the number of times class i truly occurred

• $\sum_j C_{ij}$

$\sum_j C_{ij}$ the number of times class i was predicted

• $\sum_i C_{ii}$

$\sum_i C_{ii}$ the total number of samples correctly predicted

• $\sum_i \sum_j C_{ij}$

$\sum_i \sum_j C_{ij}$ the total number of samples

Then the multiclass MCC is defined as

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

$$\frac{\sum_i C_{ii} \times \sqrt{\sum_j C_{ij} \times \sum_k C_{ik}} - \sqrt{(\sum_i C_{ii})^2 \times \sum_j \sum_k C_{jk}}}{\sqrt{(\sum_i \sum_j C_{ij})^2 - \sum_i \sum_j C_{ij}^2}}$$

When there are more than two labels the value of the MCC will no longer range between 1 and 1 Instead the minimum value will be somewhere between 1 and 0 depending on the number and distribution of ground true labels The maximum value is always 1

Here is a small example illustrating the usage of the matthewscore function

from sklearn.metrics import matthewscore

ytrue 1 1 1 1

ypred 1 1 1 1

matthewscore(ytrue, ypred)

0.33

Multilabel confusion matrix

The multilabelconfusionmatrix function computes classwise default or samplewise sample

wise True multilabel confusion matrix to evaluate the accuracy of a classification multilabelconfusionmatrix

33 Model selection and evaluation 555

scikitlearn user guide Release 0213

also treats multiclass data as if it were multilabel as this is a transformation commonly applied to evaluate multiclass problems with binary classification metrics such as precision recall etc

When calculating classwise multilabel confusion matrix the count of true negatives for class 0 is 00 false negatives is 010 true positives is 011and false positives is 01

Here is an example demonstrating the use of the multilabelconfusionmatrix function with multilabel

indicator matrix input

```
import numpy as np
from sklearn.metrics import multilabelconfusionmatrix
```

```
ytrue = np.array([0 1
```

```
0 1 0
```

```
ypred = np.array([0 0
```

```
0 1 1
```

```
multilabelconfusionmatrix(ytrue, ypred)
```

```
array([[0 1
```

```
0 1
```

```
1 0
```

```
0 1
```

```
0 1
```

```
1 0
```

Or a confusion matrix can be constructed for each sample's labels

```
multilabelconfusionmatrix(ytrue, ypred, samplewise=True)
```

```
array([[0
```

```
1 1
```

```
1 1
```

```

Receiver operating characteristic ROC

The function roccurve computes the receiver operating characteristic curve or ROC curve Quoting Wikipedia

“A receiver operating characteristic ROC or simply ROC curve is a graphical plot which illustrates the performance of a binary classifier system as its discrimination threshold is varied It is created by plotting the fraction of true positives out of the positives TPR true positive rate vs the fraction of false positives out of the negatives FPR false positive rate at various threshold settings TPR is also known as sensitivity and FPR is one minus the specificity or true negative rate”

This function requires the true binary value and the target scores which can either be probability estimates of the positive class confidence values or binary decisions Here is a small example of how to use the roccurve function

```
import numpy as np
from sklearnmetrics import roccurve
y nparray1 1 2 2
scores nparray01 04 035 08
fpr tpr thresholds roccurve scores poslabel2
fpr
array0 0 05 05 1
tpr
array0 05 05 1 1
thresholds
array18 08 04 035 01
```

scikitlearn user guide Release 0213

This figure shows an example of such an ROC curve

The `rocaucscore` function computes the area under the receiver operating characteristic ROC curve which is also denoted by AUC or AUROC. By computing the area under the ROC curve the curve information is summarized in one number. For more information see the Wikipedia article on AUC.

```
import numpy as np
from sklearn.metrics import rocaucscore
ytrue = np.array([0, 1, 1])
yscores = np.array([0.1, 0.4, 0.35, 0.8])
rocaucscore(ytrue, yscores)
0.75
```

In multilabel classification the `rocaucscore` function is extended by averaging over the labels as above. Compared to metrics such as the subset accuracy, the Hamming loss, or the F1 score, ROC doesn't require optimizing a threshold for each label. The `rocaucscore` function can also be used in multiclass classification if the predicted outputs have been binarized. In applications where a high false positive rate is not tolerable, the parameter `maxfpr` of `rocaucscore` can be used to summarize the ROC curve up to the given limit.

558 Chapter 3 User Guide

Examples

- See Receiver Operating Characteristic ROC for an example of using ROC to evaluate the quality of the output of a classifier
- See Receiver Operating Characteristic ROC with cross validation for an example of using ROC to evaluate classifier output quality using crossvalidation
- See Species distribution modeling for an example of using ROC to model species distribution

Zero one loss

The `zeroone_loss` function computes the sum or the average of the 01 classification loss $\{0,1\}$ over n samples

By default the function normalizes over the sample To get the sum of the $\{0,1\}$ set `normalize` to `False`

In multilabel classification the `zeroone_loss` scores a subset as one if its labels strictly match the predictions

and as a zero if there are any errors By default the function returns the percentage of imperfectly predicted subsets

To get the count of such subsets instead set `normalize` to `False`

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the 01 loss $\{0,1\}$ is defined as

$$\{0,1\} = 1 - \mathbb{I}(\hat{y}_i = y_i)$$

where \mathbb{I} is the indicator function

```
from sklearn.metrics import zeroone_loss
```

```
ypred = [1, 2, 3, 4]
```

```
ytrue = [2, 2, 3, 4]
```

```
zeroone_loss(ytrue, ypred)
```

- See Recursive feature elimination with crossvalidation for an example of zero one loss usage to perform recursive feature elimination with crossvalidation

Brier score loss

Thebrierscoreloss function computes the Brier score for binary classes Quoting Wikipedia

“The Brier score is a proper score function that measures the accuracy of probabilistic predictions It is applicable to tasks in which predictions must assign probabilities to a set of mutually exclusive discrete outcomes”

This function returns a score of the mean square difference between the actual outcome and the predicted probability of the possible outcome The actual outcome has to be 1 or 0 true or false while the predicted probability of the actual outcome can be a value between 0 and 1

The brier score loss is also between 0 to 1 and the lower the score the mean square difference is smaller the more accurate the prediction is It can be thought of as a measure of the “calibration” of a set of probabilistic predictions

$\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$

$\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$

$\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$

where n is the total number of predictions \hat{y}_i is the predicted probability of the actual outcome y_i

Here is a small example of usage of this function

```
import numpy as np
from sklearn.metrics import brierscoreloss

ytrue = np.array([1, 1, 0])
ytruecategorical = np.array(['spam', 'ham', 'ham', 'spam'])
yprob = np.array([0.1, 0.9, 0.8, 0.4])
ypred = np.array([0, 1, 1, 0])
brierscoreloss(ytrue, yprob)
0.055
brierscoreloss(ytrue, 1 - yprob)
0.055
brierscoreloss(ytruecategorical, yprob)
0.055
brierscoreloss(ytrue, yprob * 0.5)
0.0
```

Multilabel ranking metrics

In multilabel learning each sample can have any number of ground truth labels associated with it The goal is to give high scores and better rank to the ground truth labels

Coverage error

Thecoverageerror function computes the average number of labels that have to be included in the final prediction such that all true labels are predicted This is useful if you want to know how many topscoredlabeled you have to predict in average without missing any true one The best value of this metrics is thus the average number of true labels

Note Our implementation’s score is 1 greater than the one given in Tsoumakas et al 2010 This extends it to handle the degenerate case in which an instance has 0 true labels

Formally given a binary indicator matrix of the ground truth labels $y \in \{0,1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $s \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ the coverage is defined as

$$\text{coverage} = \frac{1}{n_{\text{samples}}} \sum_{i=1}^{n_{\text{samples}}} \min_{j \in \{1, \dots, n_{\text{labels}}\}} \{s_{ij} \mid y_{ij} = 1\}$$

with rank r_{ij}

$r_{ij} \geq r_{ik}$ Given the rank definition ties in yscores are broken by giving the maximal rank that would have been assigned to all tied values

Here is a small example of usage of this function

```
import numpy as np
from sklearn.metrics import coverageerror

ytrue = np.array([0, 0, 0, 0, 1])
yscore = np.array([0.75, 0.5, 1, 1, 0.2])
coverageerror(ytrue, yscore)
25
```

Label ranking average precision

Thelabelrankingaverageprecisionscore function implements label ranking average precision LRAP This metric is linked to the averageprecisionscore function but is based on the notion of label ranking instead of precision and recall

Label ranking average precision LRAP averages over the samples the answer to the following question for each ground truth label what fraction of higherranked labels were true labels This performance measure will be higher if you are able to give better rank to the labels associated with each sample The obtained score is always strictly greater than 0 and the best value is 1 If there is exactly one relevant label per sample label ranking average precision is equivalent to the mean reciprocal rank

Formally given a binary indicator matrix of the ground truth labels $y \in \{0,1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $s \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ the average precision is defined as

$$\text{LRAP} = \frac{1}{n_{\text{samples}}} \sum_{i=1}^{n_{\text{samples}}} \frac{1}{\text{rank}_i} \sum_{j=1}^{\text{rank}_i} y_{ij}$$

where rank_i is the rank of the i -th sample, i.e. the number of elements in the set $\{j \mid y_{ij} = 1\}$ and $\|\cdot\|_0$ is the ℓ_0 “norm” which computes the number of nonzero elements in a vector

Here is a small example of usage of this function

```
import numpy as np
from sklearn.metrics import label_ranking_average_precision_score
y_true = np.array([0, 0, 0, 0, 1])
y_score = np.array([0.75, 0.5, 1, 1, 0.2])
label_ranking_average_precision_score(y_true, y_score)
0.416
```

Ranking loss

The `label_ranking_loss` function computes the ranking loss which averages over the samples the number of label pairs that are incorrectly ordered ie true labels have a lower score than false labels weighted by the inverse of the number of ordered pairs of false and true labels The lowest achievable ranking loss is zero

Formally given a binary indicator matrix of the ground truth labels $y \in \{0,1\}^{n_{\text{samples}} \times n_{\text{labels}}}$ and the score associated with each label $s \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ the ranking loss is defined as

$$\text{Ranking Loss} = \frac{1}{n_{\text{samples}}} \sum_{i=1}^{n_{\text{samples}}} \frac{1}{\binom{n_{\text{labels}}}{2}} \sum_{j_1 < j_2} (y_{ij_1} - y_{ij_2}) (s_{ij_1} - s_{ij_2})$$

where $\binom{n}{2}$ computes the cardinality of the set ie the number of elements in the set and $\|\cdot\|_0$ is the ℓ_0 “norm” which computes the number of nonzero elements in a vector

Here is a small example of usage of this function

```
import numpy as np
from sklearn.metrics import label_ranking_loss
y_true = np.array([0, 0, 0, 0, 1])
y_score = np.array([0.75, 0.5, 1, 1, 0.2])
label_ranking_loss(y_true, y_score)
0.75
```

With the following prediction we have perfect and minimal loss

```
y_score = np.array([0, 1, 0.2, 0.1, 0.2, 0.9])
label_ranking_loss(y_true, y_score)
0.0
```

Regression metrics

The sklearn.metrics module implements several loss score and utility functions to measure regression performance Some of those have been enhanced to handle the multioutput case meansquarederror meanabsoluteerror explainedvariancescore and r2score

These functions have an multioutput keyword argument which specifies the way the scores or losses for each individual target should be averaged The default is uniformaverage which specifies a uniformly weighted mean over outputs If an ndarray of shape noutputs is passed then its entries are interpreted as weights and an according weighted average is returned If multioutput israwvalues is specified then all unaltered individual scores or losses will be returned in an array of shape noutputs Ther2score and explainedvariancescore accept an additional value varianceweighted for themultioutput parameter This option leads to a weighting of each individual score by the variance of the corresponding target variable This setting quantifies the globally captured unscaled variance If the target variables are of different scale then this score puts more importance on well explaining the higher variance variables multioutputvarianceweighted is the default value for r2score for backward compatibility This will be changed to uniformaverage in the future

Explained variance score

The explainedvariancescore computes the explained variance regression score

If \hat{y} is the estimated target output y the corresponding correct target output and σ^2 is Variance the square of the standard deviation then the explained variance is estimated as follow

$$\text{Explained Variance Score} = 1 - \frac{\text{Residual Sum of Squares}}{\text{Total Sum of Squares}}$$

or

The best possible score is 1.0 lower values are worse

Here is a small example of usage of the explainedvariancescore function

```
from sklearn.metrics import explainedvariancescore
ytrue = [3, 0.5, 2, 7]
ypred = [2.5, 0.0, 2, 8]
explainedvariancescore(ytrue, ypred)
0.957
ytrue = [0.5, 1, 1, 1, 7, 6]
ypred = [0, 2, 1, 2, 8, 5]
explainedvariancescore(ytrue, ypred, multioutput='raw_values')
```

```
array(0.967, 1)
explainedvariancescore(ytrue, ypred, multioutput='raw_values')
```

Max error

The `maxerror` function computes the maximum residual error a metric that captures the worst case error between the predicted value and the true value In a perfectly fitted single output regression model `maxerror` would be 0 on the training set and though this would be highly unlikely in the real world this metric shows the extent of error that the model had when it was fitted

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the max error is defined as

$$\text{Max Error} = \max_i | \hat{y}_i - y_i |$$

Here is a small example of usage of the `maxerror` function

```
from sklearn.metrics import maxerror
ytrue = [3, 2, 7, 1]
ypred = [9, 2, 7, 1]
maxerror(ytrue, ypred)
6
```

The `maxerror` does not support multioutput

Mean absolute error

The `meanabsoluteerror` function computes mean absolute error a risk metric corresponding to the expected value of the absolute error loss or ℓ_1 norm loss

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the mean absolute error

MAE estimated over n samples is defined as

$$\text{MAE} = \frac{1}{n} \sum_{i=1}^n | \hat{y}_i - y_i |$$

Here is a small example of usage of the `meanabsoluteerror` function

```
from sklearn.metrics import meanabsoluteerror
ytrue = [3, 0.5, 2, 7]
ypred = [2.5, 0.0, 2, 8]
meanabsoluteerror(ytrue, ypred)
0.5
ytrue = [0.5, 1, 1, 1, 7, 6]
ypred = [0, 2, 1, 2, 8, 5]
meanabsoluteerror(ytrue, ypred)
0.75
meanabsoluteerror(ytrue, ypred, multioutput='raw_values')
array([0.5, 1])
meanabsoluteerror(ytrue, ypred, multioutput=(0.3, 0.7))
```

085

Mean squared error

The `meansquarederror` function computes mean square error a risk metric corresponding to the expected value of the squared quadratic error or loss

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the mean squared error MSE estimated over n samples is defined as

$$MSE = \frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2$$

Here is a small example of usage of the meansquarederror function

```
from sklearn.metrics import meansquarederror
ytrue = 3 05 2 7
ypred = 25 00 2 8
meansquarederror(ytrue, ypred)
0.375
ytrue = 05 1 1 1 7 6
ypred = 0 2 1 2 8 5
meansquarederror(ytrue, ypred)
0.7083
```

- Examples
- See Gradient Boosting regression for an example of mean squared error usage to evaluate gradient boosting regression

Mean squared logarithmic error

The meansquaredlogerror function computes a risk metric corresponding to the expected value of the squared logarithmic quadratic error or loss

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the mean squared logarithmic error MSLE estimated over n samples is defined as

$$MSLE = \frac{1}{n} \sum_{i=1}^n (\log y_i - \log \hat{y}_i)^2$$

Where \log means the natural logarithm of x . This metric is best to use when targets having exponential growth such as population counts average sales of a commodity over a span of years etc. Note that this metric penalizes an underpredicted estimate greater than an overpredicted estimate.

Here is a small example of usage of the meansquaredlogerror function

```
from sklearn.metrics import meansquaredlogerror
ytrue = 3 5 25 7
ypred = 25 5 4 8
meansquaredlogerror(ytrue, ypred)
0.039
ytrue = 05 1 1 2 7 6
ypred = 05 2 1 25 8 8
meansquaredlogerror(ytrue, ypred)
0.044
```

Median absolute error

The medianabsoluteerror is particularly interesting because it is robust to outliers. The loss is calculated by taking the median of all absolute differences between the target and the prediction.

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value then the median absolute error

MedAE estimated over n samples is defined as

$$\text{MedAE} = \text{median}(|\hat{y}_1 - y_1|, \dots, |\hat{y}_n - y_n|)$$

The medianabsoluteerror does not support multioutput

Here is a small example of usage of the medianabsoluteerror function

```
from sklearn.metrics import medianabsoluteerror
ytrue = 3 05 2 7
ypred = 25 00 2 8
medianabsoluteerror(ytrue, ypred)
05
```

R2score the coefficient of determination

The r2score function computes the coefficient of determination usually denoted as R^2

It represents the proportion of variance of y that has been explained by the independent variables in the model. It provides an indication of goodness of fit and therefore a measure of how well unseen samples are likely to be predicted by the model through the proportion of explained variance.

As such variance is dataset dependent R^2 may not be meaningfully comparable across different datasets. Best possible score is 1.0 and it can be negative because the model can be arbitrarily worse. A constant model that always predicts the expected value of y , disregarding the input features, would get a R^2 score of 0.0.

If \hat{y}_i is the predicted value of the i th sample and y_i is the corresponding true value for total n samples the estimated R^2 is defined as

$$R^2 = 1 - \frac{\sum_{i=1}^n (\hat{y}_i - \bar{y})^2}{\sum_{i=1}^n (y_i - \bar{y})^2}$$

where $\bar{y} = \frac{1}{n} \sum_{i=1}^n y_i$

Note that r2score calculates unadjusted R^2 without correcting for bias in sample variance of y

Here is a small example of usage of the r2score function

```
from sklearn.metrics import r2score
ytrue = 3 05 2 7
ypred = 25 00 2 8
r2score(ytrue, ypred)
0.948
ytrue = 0.5 1 1 1 7 6
ypred = 0 2 1 2 8 5
r2score(ytrue, ypred, multioutput='variance_weighted')
```

```
0.938
ytrue = 0.5 1 1 1 7 6
ypred = 0 2 1 2 8 5
r2score(ytrue, ypred, multioutput='uniform_average')
```

```
0.936
r2score(ytrue, ypred, multioutput='raw_values')
```

```
array(0.965, 0.908)
r2score(ytrue, ypred, multioutput=(0.3, 0.7))
566 Chapter 3 User Guide
```

Example

- See Lasso and Elastic Net for Sparse Signals for an example of R2score usage to evaluate Lasso and Elastic Net on sparse signals

Clustering metrics

The sklearn.metrics module implements several loss score and utility functions For more information see the Clustering performance evaluation section for instance clustering and Biclustering evaluation for biclustering

Dummy estimators

When doing supervised learning a simple sanity check consists of comparing one's estimator against simple rules of thumb DummyClassifier implements several such simple strategies for classification

- stratified generates random predictions by respecting the training set class distribution
- mostfrequent always predicts the most frequent label in the training set
- prior always predicts the class that maximizes the class prior like mostfrequent and predict_proba returns the class prior
- uniform generates predictions uniformly at random
- constant always predicts a constant label that is provided by the user A major motivation of this method is F1scoring when the positive class is in the minority

Note that with all these strategies the predict method completely ignores the input data

To illustrate DummyClassifier first let's create an imbalanced dataset

```
from sklearn.datasets import load_iris
from sklearn.model_selection import train_test_split
iris = load_iris
X, y = iris.data, iris.target
y[y == 1] = 0
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
```

Next let's compare the accuracy of SVC (Support Vector Classification) and mostfrequent

```
from sklearn.dummy import DummyClassifier
from sklearn.svm import SVC
clf = SVC(kernel='linear', C=1)
clf.fit(X_train, y_train)
clf.score(X_test, y_test)
```

```
0.63
clf = DummyClassifier(strategy='mostfrequent', random_state=0)
clf.fit(X_train, y_train)
```

```
DummyClassifier(constant=None, random_state=0, strategy='mostfrequent')
clf.score(X_test, y_test)
```

0.57

We see that SVC (Support Vector Classification) doesn't do much better than a dummy classifier Now let's change the kernel

```
scikitlearn user guide Release 0213
clf SVCgamma scale kernelrbf C1fitXtrain ytrain
clf scoreXtest ytest
094
```

We see that the accuracy was boosted to almost 100 A cross validation strategy is recommended for a better estimate of the accuracy if it is not too CPU costly For more information see the Crossvalidation evaluating estimator performance section Moreover if you want to optimize over the parameter space it is highly recommended to use an appropriate methodology see the Tuning the hyperparameters of an estimator section for details More generally when the accuracy of a classifier is too close to random it probably means that something went wrong features are not helpful a hyperparameter is not correctly tuned the classifier is suffering from class imbalance etc DummyRegressor also implements four simple rules of thumb for regression

- mean always predicts the mean of the training targets
 - median always predicts the median of the training targets
 - quantile always predicts a user provided quantile of the training targets
 - constant always predicts a constant value that is provided by the user
- In all these strategies the predict method completely ignores the input data

334 Model persistence

After training a scikitlearn model it is desirable to have a way to persist the model for future use without having to retrain The following section gives you an example of how to persist a model with pickle We'll also review a few security and maintainability issues when working with pickle serialization

An alternative to pickling is to export the model to another format using one of the model export tools listed under Related Projects Unlike pickling once exported you cannot recover the full Scikitlearn estimator object but you can deploy the model for prediction usually by using tools supporting open model interchange formats such as 'ONNX' or 'PMML'

Persistence example

It is possible to save a model in scikitlearn by using Python's builtin persistence model namely pickle

```
from sklearn import svm
from sklearn import datasets
clf svmSVCgamma scale
iris datasetsloadiris
X y irisdata iristarget
clf fitX y
SVCC10 cachesize200 classweightNone coef000
decisionfunctionshapeovr degree3 gamma scale kernelrbf
maxiter1 probabilityFalse randomstateNone shrinkingTrue
tol0001 verboseFalse
import pickle
s pickledumpsclf
clf2 pickleloadss
clf2predictX01
array0
y0
0
```

scikitlearn user guide Release 0213

In the specific case of scikitlearn it may be better to use joblib’s replacement of pickle dump load which is more efficient on objects that carry large numpy arrays internally as is often the case for fitted scikitlearn estimators but can only pickle to the disk and not to a string

```
from joblib import dump load
dumpclf filenamejoblib
```

Later you can load back the pickled model possibly in another Python process with
clf loadfilenamejoblib

Notedump andload functions also accept filelike object instead of filenames More information on data persis
tence with Joblib is available here

Security maintainability limitations

pickle and joblib by extension has some issues regarding maintainability and security Because of this

- Never unpickle untrusted data as it could lead to malicious code being executed upon loading
- While models saved using one version of scikitlearn might load in other versions this is entirely unsupported and inadvisable It should also be kept in mind that operations performed on such data could give different and unexpected results

In order to rebuild a similar model with future versions of scikitlearn additional metadata should be saved along the pickled model

- The training data eg a reference to an immutable snapshot
- The python source code used to generate the model
- The versions of scikitlearn and its dependencies
- The cross validation score obtained on the training data

This should make it possible to check that the crossvalidation score is in the same range as before

Since a model internal representation may be different on two different architectures dumping a model on one archi
tecture and loading it on another architecture is not supported

If you want to know more about these issues and explore other possible serialization methods please refer to this talk
by Alex Gaynor

335 Validation curves plotting scores to evaluate models

Every estimator has its advantages and drawbacks Its generalization error can be decomposed in terms of bias
variance and noise The bias of an estimator is its average error for different training sets The variance of an
estimator indicates how sensitive it is to varying training sets Noise is a property of the data

In the following plot we see a function $y = \cos(3x)$

2D and some noisy samples from that function We use three
different estimators to fit the function linear regression with polynomial features of degree 1 4 and 15 We see that
the first estimator can at best provide only a poor fit to the samples and the true function because it is too simple
high bias the second estimator approximates it almost perfectly and the last estimator approximates the training data
perfectly but does not fit the true function very well ie it is very sensitive to varying training data high variance
Bias and variance are inherent properties of estimators and we usually have to select learning algorithms and hyper
parameters so that both bias and variance are as low as possible see Biasvariance dilemma Another way to reduce

33 Model selection and evaluation 569

the variance of a model is to use more training data However you should only collect more training data if the true function is too complex to be approximated by an estimator with a lower variance
In the simple onedimensional problem that we have seen in the example it is easy to see whether the estimator suffers from bias or variance However in highdimensional spaces models can become very difficult to visualize For this reason it is often helpful to use the tools described below

Examples

- Underfitting vs Overfitting
- Plotting Validation Curves
- Plotting Learning Curves

Validation curve

To validate a model we need a scoring function see Model evaluation quantifying the quality of predictions for example accuracy for classifiers The proper way of choosing multiple hyperparameters of an estimator are of course grid search or similar methods see Tuning the hyperparameters of an estimator that select the hyperparameter with the maximum score on a validation set or multiple validation sets Note that if we optimized the hyperparameters based on a validation score the validation score is biased and not a good estimate of the generalization any longer To get a proper estimate of the generalization we have to compute the score on another test set

However it is sometimes helpful to plot the influence of a single hyperparameter on the training score and the validation score to find out whether the estimator is overfitting or underfitting for some hyperparameter values

The function validationcurve can help in this case

```
import numpy as np
from sklearn.model_selection import validationcurve
from sklearn.datasets import loadiris
from sklearn.linear_model import Ridge
np.random.seed(0)
iris = loadiris()
X, y = iris.data, iris.target
indices = np.arange(y.shape[0])
np.random.shuffle(indices)
570 Chapter 3 User Guide
```

090 084 094 096 093

046 025 050 049 052

If the training score and the validation score are both low the estimator will be underfitting If the training score is high and the validation score is low the estimator is overfitting and otherwise it is working very well A low training score and a high validation score is usually not possible All three cases can be found in the plot below where we vary the parameter α of an SVM (Support Vector Machine) on the digits dataset

Learning curve

A learning curve shows the validation and training score of an estimator for varying numbers of training samples It is a tool to find out how much we benefit from adding more training data and whether the estimator suffers more from a variance error or a bias error If both the validation score and the training score converge to a value that is too low with increasing size of the training set we will not benefit much from more training data In the following plot you can see an example naive Bayes roughly converges to a low score

We will probably have to use an estimator or a parametrization of the current estimator that can learn more complex concepts ie has a lower bias If the training score is much greater than the validation score for the maximum number of training samples adding more training samples will most likely increase generalization In the following plot you can see that the SVM (Support Vector Machine) could benefit from more training examples

We can use the function learningcurve to generate the values that are required to plot such a learning curve number of samples that have been used the average scores on the training sets and the average scores on the validation sets

from sklearnmodelselection import learningcurve

34 Inspection

341 Partial dependence plots

Partial dependence plots PDP show the dependence between the target response1and a set of ‘target’ features marginalizing over the values of all other features the ‘complement’ features Intuitively we can interpret the partial dependence as the expected target response as a function of the ‘target’ features

Due to the limits of human perception the size of the target feature set must be small usually one or two thus the target features are usually chosen among the most important features

The figure below shows four oneway and one twoway partial dependence plots for the California housing dataset with aGradientBoostingRegressor

Oneway PDPs tell us about the interaction between the target response and the target feature eg linear nonlinear

The upper left plot in the above figure shows the effect of the median income in a district on the median house price

1For classification the target response may be the probability of a class the positive class for binary classification or the decision function

34 Inspection 573

scikitlearn user guide Release 0213

we can clearly see a linear relationship among them Note that PDPs assume that the target features are independent from the complement features and this assumption is often violated in practice

PDPs with two target features show the interactions among the two features For example the twovariable PDP in the above figure shows the dependence of median house price on joint values of house age and average occupants per household We can clearly see an interaction between the two features for an average occupancy greater than two the house price is nearly independent of the house age whereas for values less than 2 there is a strong dependence on age The sklearninspection module provides a convenience function plotpartialdependence to create

oneway and twoway partial dependence plots In the below example we show how to create a grid of partial dependence plots two oneway PDPs for the features 0 and 1 and a twoway PDP between the two features

```
from sklearn.datasets import make_hastie102
from sklearn.ensemble import GradientBoostingClassifier
from sklearn.inspection import plot_partial_dependence
X, y = make_hastie102(random_state=0)
clf = GradientBoostingClassifier(n_estimators=100, learning_rate=10,
                                max_depth=1, random_state=0)
fit = clf.fit(X, y)
features = [0, 1, 0, 1]
plot_partial_dependence(clf, X, features)
```

You can access the newly created figure and Axes objects using plt.gcf() and plt.gca()

For multiclass classification you need to set the class label for which the PDPs should be created via the target argument

```
from sklearn.datasets import load_iris
iris = load_iris()
mc_clf = GradientBoostingClassifier(n_estimators=10,
                                    max_depth=1)
fit = mc_clf.fit(iris.data, iris.target)
features = [3, 2, 3, 2]
plot_partial_dependence(mc_clf, X, features, target=0)
```

The same parameter target is used to specify the target in multioutput regression settings

If you need the raw values of the partial dependence function rather than the plots you can use the sklearn

inspection.partialdependence function

```
from sklearn.inspection import partial_dependence
pdp, axes = partial_dependence(clf, X, [0])
pdp
array(2466, 2466)
axes
array(1624, 1592)
```

The values at which the partial dependence should be evaluated are directly generated from X For 2way partial dependence a 2D grid of values is generated The values field returned by sklearn.inspection.partialdependence gives the actual values used in the grid for each target feature They also correspond to the axis of the plots

For each value of the 'target' features in the grid the partial dependence function needs to marginalize the predictions of the estimator over all possible values of the 'complement' features With the brute method this is done by replacing every target feature value of X by those in the grid and computing the average prediction In decision trees this can be evaluated efficiently without reference to the training data recursion method For each grid point a weighted tree traversal is performed if a split node involves a 'target' feature the corresponding left or right branch is followed otherwise both branches are followed each branch is weighted by the fraction of

scikitlearn user guide Release 0213

training samples that entered that branch Finally the partial dependence is given by a weighted average of all visited leaves Note that with the recursion method X is only used to generate the grid not to compute the averaged predictions The averaged predictions will always be computed on the data with which the trees were trained

Examples

- Partial Dependence Plots

References

35 Dataset transformations

scikitlearn provides a library of transformers which may clean see Preprocessing data reduce see Unsupervised dimensionality reduction expand see Kernel Approximation or generate see Feature extraction feature representations

Like other estimators these are represented by classes with a fit method which learns model parameters eg mean and standard deviation for normalization from a training set and a transform method which applies this transformation model to unseen data fittransform may be more convenient and efficient for modelling and transforming the training data simultaneously

Combining such transformers either in parallel or series is covered in Pipelines and composite estimators Pair wise metrics Affinities and Kernels covers transforming feature spaces into affinity matrices while Transforming the prediction target y considers transformations of the target space eg categorical labels for use in scikitlearn

351 Pipelines and composite estimators

Transformers are usually combined with classifiers regressors or other estimators to build a composite estimator The most common tool is a Pipeline Pipeline is often used in combination with FeatureUnion which concatenates the output of transformers into a composite feature space TransformedTargetRegressor deals with transforming the target ie logtransform y In contrast Pipelines only transform the observed data X

Pipeline chaining estimators

Pipeline can be used to chain multiple estimators into one This is useful as there is often a fixed sequence of steps in processing the data for example feature selection normalization and classification Pipeline serves multiple purposes here

Convenience and encapsulation You only have to call fit and predict once on your data to fit a whole sequence of estimators

Joint parameter selection You can grid search over parameters of all estimators in the pipeline at once

Safety Pipelines help avoid leaking statistics from your test data into the trained model in crossvalidation by ensuring that the same samples are used to train the transformers and predictors

All estimators in a pipeline except the last one must be transformers ie must have a transform method The last estimator may be any type transformer classifier etc

35 Dataset transformations 575

Usage

Construction

ThePipeline is built using a list of key value pairs where the key is a string containing the name you want to give this step and value is an estimator object

```
from sklearnpipeline import Pipeline
from sklearnsvm import SVC (Support Vector Classification)
from sklearndecomposition import PCA (Principal Component Analysis)
estimators reducedim PCA (Principal Component Analysis) clf SVC (Support Vector Classification)
pipe Pipelineestimators
pipe
PipelinememoryNone
stepsreducedim PCAcopyTrue
clf SVCC10 verboseFalse
```

The utility function makepipeline is a shorthand for constructing pipelines it takes a variable number of estimators and returns a pipeline filling in the names automatically

```
from sklearnpipeline import makepipeline
from sklearnnaivebayes import MultinomialNB
from sklearnpreprocessing import Binarizer
makepipelineBinarizer MultinomialNB
PipelinememoryNone
stepsbinarizer BinarizercopyTrue threshold00
multinomialnb MultinomialNBalpha10
classpriorNone
fitpriorTrue
verboseFalse
```

Accessing steps

The estimators of a pipeline are stored as a list in the steps attribute but can be accessed by index or name by indexing with idx the Pipeline

```
pipesteps0
reducedim PCAcopyTrue iteratedpowerauto ncomponentsNone
randomstateNone svdsolverauto tol00
whitenFalse
```

```
pipe0
PCAcopyTrue iteratedpowerauto ncomponentsNone randomstateNone
svdsolverauto tol00 whitenFalse
```

```
pipereducedim
PCAcopyTrue
```

Pipeline’snamedsteps attribute allows accessing steps by name with tab completion in interactive environments
pipenamedstepsreducedim ispipereducedim
True

A subpipeline can also be extracted using the slicing notation commonly used for Python Sequences such as lists or strings although only a step of 1 is permitted This is convenient for performing only some of the transformations or their inverse

scikitlearn user guide Release 0213

```
pipe1
Pipeline(memory=None, steps=[Step1, PCA(copy=True)
```

```
pipe1
Pipeline(memory=None, steps=[Step1, SVC(C10)
```

Nested parameters
Parameters of the estimators in the pipeline can be accessed using the estimatorparameter syntax

```
pipe.set_params(C10)
Pipeline(memory=None,
steps=[Step1, PCA(copy=True, iterated_power=auto)
clf = SVC(C10, cache_size=200, class_weight=None,
verbose=False)
```

This is particularly important for doing grid searches

```
from sklearn.model_selection import GridSearchCV
param_grid = {'Step1__C10': [2, 5, 10],
               'Step1__C01': [10, 100]}
```

```
grid_search = GridSearchCV(pipe, param_grid, param_grid)
```

Individual steps may also be replaced as parameters and nonfinal steps may be ignored by setting them to passthrough

```
from sklearn.linear_model import LogisticRegression
param_grid = {'Step1__C10': [5, 10],
               'Step2__C10': [5, 10],
               'Step3__C10': [5, 10]}
```

```
grid_search = GridSearchCV(pipe, param_grid, param_grid)
```

The estimators of the pipeline can be retrieved by index

```
pipe[0]
pipe.steps[0][1]
pipe.steps[0][1].get_params()
pipe.steps[0][1].set_params()
```

- Examples

 - SVMAnova SVM (Support Vector Machine) with univariate feature selection
 - Selecting dimensionality reduction with Pipeline and GridSearchCV

35 Dataset transformations 577

scikitlearn user guide Release 0213

See also

- Tuning the hyperparameters of an estimator

Notes

Callingfit on the pipeline is the same as calling fit on each estimator in turn transform the input and pass it on to the next step The pipeline has all the methods that the last estimator in the pipeline has ie if the last estimator is a classifier the Pipeline can be used as a classifier If the last estimator is a transformer again so is the pipeline Caching transformers avoid repeated computation

Fitting transformers may be computationally expensive With its memory parameter set Pipeline will cache each transformer after calling fit This feature is used to avoid computing the fit transformers within a pipeline if the parameters and input data are identical A typical example is the case of a grid search in which the transformers can be fitted only once and reused for each configuration

The parameter memory is needed in order to cache the transformers memory can be either a string containing the directory where to cache the transformers or a joblibMemory object

```
from tempfile import mkdtemp
from shutil import rmtree
from sklearn.decomposition import PCA (Principal Component Analysis)
from sklearn.svm import SVC (Support Vector Classification)
from sklearn.pipeline import Pipeline
estimators = reducedim PCA (Principal Component Analysis) clf SVC (Support Vector Classification)
cachedir = mkdtemp
pipe = Pipeline(estimators, memory=cachedir)
pipe
Pipeline
steps=reducedim PCA(copy=True)
clf = SVCC10 verbose=False
Clear the cache directory when you dont need it anymore
rmtree(cachedir)
```

Warning Side effect of caching transformers

Using aPipeline without cache enabled it is possible to inspect the original instance such as

```
from sklearn.datasets import load_digits
digits = load_digits
pca1 = PCA (Principal Component Analysis)
svm1 = SVC(gamma=scale)
pipe = Pipeline(reducedim(pca1), clf=svm1)
pipe.fit(digits.data, digits.target)
```

Pipeline.memory=None

```
steps=reducedim PCA (Principal Component Analysis) clf SVC (Support Vector Classification)
verbose=False
```

The pca instance can be inspected directly

```
print(pca.components_
177484909e19 407058917e18
```

scikitlearn user guide Release 0213

Enabling caching triggers a clone of the transformers before fitting Therefore the transformer instance given to the pipeline cannot be inspected directly In following example accessing the PCA (Principal Component Analysis) instance `pca2` will raise an `AttributeError` since `pca2` will be an unfitted transformer Instead use the attribute named `steps` to inspect estimators within the pipeline

```
cachedir = makedirs
pca2 = PCA (Principal Component Analysis)
svm2 = SVCgamma=scale
cachedpipe = Pipeline(reducedim=pca2, clf=svm2)
memorycachedir =
cachedpipe.fit(digits.data, digits.target)
```

`Pipeline(memory=steps=reducedim.PCA (Principal Component Analysis), clf=SVC (Support Vector Classification), verbose=False, print_cached_pipe_named_steps=reducedim.components)`

177484909e19 407058917e18

Remove the cache directory

`rmtree(cachedir)`

Examples

•Selecting dimensionality reduction with Pipeline and GridSearchCV

Transforming target in regression

`TransformedTargetRegressor` transforms the targets `y` before fitting a regression model The predictions are mapped back to the original space via an inverse transform It takes as an argument the regressor that will be used for prediction and the transformer that will be applied to the target variable

```
import numpy as np
from sklearn.datasets import load_boston
from sklearn.compose import TransformedTargetRegressor
from sklearn.preprocessing import QuantileTransformer
from sklearn.linear_model import LinearRegression
from sklearn.model_selection import train_test_split

boston = load_boston()
X, boston_data, y, boston_target =
transformer = QuantileTransformer(output_distribution='normal')
regressor = LinearRegression()
regr = TransformedTargetRegressor(regressor=regressor,
transformer=transformer)
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
regr.fit(X_train, y_train)
TransformedTargetRegressor
print(R2_score(y_test, regr.predict(X_test)))
R2 score 0.67
raw_target_regr = LinearRegression().fit(X_train, y_train)
print(R2_score(y_test, raw_target_regr.predict(X_test)))
R2 score 0.64
```

35 Dataset transformations 579

scikitlearn user guide Release 0213

For simple transformations instead of a Transformer object a pair of functions can be passed defining the transformation and its inverse mapping

```
def funcx
return nplogx
def inversefuncx
return npexpx
```

Subsequently the object is created as

```
regr = TransformedTargetRegressor(regressor=regressor
func=func
inversefunc=inversefunc
regr.fit(Xtrain, ytrain)
TransformedTargetRegressor
print(R2_score(0.2, format(regressor.score(Xtest, ytest)
R2_score(0.65)
```

By default the provided functions are checked at each fit to be the inverse of each other. However it is possible to bypass this checking by setting `check_inverse` to `False`

```
def inversefuncx
return x
regr = TransformedTargetRegressor(regressor=regressor
func=func
inversefunc=inversefunc
check_inverse=False
regr.fit(Xtrain, ytrain)
TransformedTargetRegressor
print(R2_score(0.2, format(regressor.score(Xtest, ytest)
R2_score(0.45)
```

Note: The transformation can be triggered by setting either `transformer` or the pair of functions `func` and `inversefunc`. However setting both options will raise an error.

Examples

- Effect of transforming the targets in regression model

FeatureUnion composite feature spaces

FeatureUnion combines several transformer objects into a new transformer that combines their output. A

FeatureUnion takes a list of transformer objects. During fitting each of these is fit to the data independently.

The transformers are applied in parallel and the feature matrices they output are concatenated side-by-side into a larger matrix.

When you want to apply different transformations to each field of the data see the related class `sklearn.compose`

`ColumnTransformer` see user guide

FeatureUnion serves the same purposes as **Pipeline** for convenience and joint parameter estimation and validation.

FeatureUnion and **Pipeline** can be combined to create complex models.

scikitlearn user guide Release 0213

AFeatureUnion has no way of checking whether two transformers might produce identical features It only produces a union when the feature sets are disjoint and making sure they are the caller’s responsibility Usage

AFeatureUnion is built using a list of key value pairs where the key is the name you want to give to a given transformation an arbitrary string it only serves as an identifier and value is an estimator object

```
from sklearn.pipeline import FeatureUnion
from sklearn.decomposition import PCA (Principal Component Analysis)
from sklearn.decomposition import KernelPCA
estimators = linearpca PCA (Principal Component Analysis) kernelpca KernelPCA
combined = FeatureUnion(estimators
combined
```

```
FeatureUnion(njobs=None
transformerlist=linearpca PCA(copy=True)
kernelpca KernelPCA(alpha=10)
transformerweights=None verbose=False
```

Like pipelines feature unions have a shorthand constructor called makeunion that does not require explicit naming of the components
LikePipeline individual steps may be replaced using setparams and ignored by setting to drop
combinedsetparamskernelpcadrop

```
FeatureUnion(njobs=None
transformerlist=linearpca PCA(copy=True)
kernelpca drop
transformerweights=None verbose=False
```

Examples
•Concatenating multiple feature extraction methods
ColumnTransformer for heterogeneous data

Warning ThecomposeColumnTransformer class is experimental and the API (Application Programming Interface) is subject to change
Many datasets contain features of different types say text floats and dates where each type of feature requires separate preprocessing or feature extraction steps Often it is easiest to preprocess data before applying scikitlearn methods for example using pandas Processing your data before passing it to scikitlearn might be problematic for one of the following reasons

- 1 Incorporating statistics from test data into the preprocessors makes crossvalidation scores unreliable known as data leakage for example in the case of scalers or imputing missing values
 - 2 You may want to include the parameters of the preprocessors in a parameter search
- TheColumnTransformer helps performing different transformations for different columns of the data within a Pipeline that is safe from data leakage and that can be parametrized ColumnTransformer works on arrays sparse matrices and pandas DataFrames
35 Dataset transformations 581

scikitlearn user guide Release 0213

To each column a different transformation can be applied such as preprocessing or a specific feature extraction method

```
import pandas as pd
X = pd.DataFrame(
    city=[London, London, Paris, Sallisaw],
    title=[His Last Bow, How Watson Learned the Trick,
           A Moveable Feast, The Grapes of Wrath],
    expertrating=[5, 3, 4, 5],
    userrating=[4, 5, 4, 3])
```

For this data we might want to encode the city column as a categorical variable using preprocessing OneHotEncoder but apply a featureextractiontextCountVectorizer to the title column. As we might use multiple feature extraction methods on the same column we give each transformer a unique name say citycategory and titlebow. By default the remaining rating columns are ignored.

```
remainderdrop
from sklearn.compose import ColumnTransformer
from sklearn.feature_extraction.text import CountVectorizer
from sklearn.preprocessing import OneHotEncoder
columntrans = ColumnTransformer(
    citycategory=OneHotEncoder(dtype=int),
    titlebow=CountVectorizer(),
    remainderdrop=True)
columntrans.fit(X)
ColumnTransformer(n_jobs=None, remainderdrop=True, sparse_threshold=0.3,
transformer_weights=None, transformers=[
columntrans.get_feature_names()
```

```
citycategoryx0=London, citycategoryx0=Paris, citycategoryx0=Sallisaw,
titlebowbow, titlebowfeast, titlebowgrapes, titlebowhis,
titlebowhow, titlebowlast, titlebowlearned, titlebowmoveable,
titlebowof, titlebowthe, titlebowtrick, titlebowwatson,
titlebowwrath,
columntranstransformXtoarray
```

```
array([[1, 0, 0, 1, 0, 0, 1, 0, 1, 0, 0, 0, 0, 0, 0, 0],
       [1, 0, 0, 0, 0, 0, 1, 0, 1, 0, 0, 1, 1, 1, 0, 0],
       [0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 0, 0],
       [0, 0, 1, 0, 0, 1, 0, 0, 0, 0, 0, 1, 1, 0, 0, 1]])
```

In the above example the CountVectorizer expects a 1D array as input and therefore the columns were specified as a string 'title'. However preprocessingOneHotEncoder as most of other transformers expects 2D data therefore in that case you need to specify the column as a list of strings ['city']. Apart from a scalar or a single item list the column selection can be specified as a list of multiple items, an integer array, a slice or a boolean mask. Strings can reference columns if the input is a DataFrame, integers are always interpreted as the positional columns.

We can keep the remaining rating columns by setting remainder=pass through. The values are appended to the end of the transformation.

```
columntrans = ColumnTransformer(
    citycategory=OneHotEncoder(dtype=int),
```

```
scikitlearn user guide Release 0213
titlebow CountVectorizer title
remainderpassthrough
columntransfittransformX
```

```
array1 0 0 1 0 0 1 0 1 0 0 0 0 0 0 5 4
1 0 0 0 0 0 0 1 0 1 0 0 1 1 1 0 3 5
0 1 0 0 1 0 0 0 0 0 1 0 0 0 0 0 4 4
0 0 1 0 0 1 0 0 0 0 0 1 1 0 0 1 5 3
```

```
Theremainder parameter can be set to an estimator to transform the remaining rating columns The transformed
values are appended to the end of the transformation
from sklearnpreprocessing import MinMaxScaler
columntrans ColumnTransformer
citycategory OneHotEncoder city
titlebow CountVectorizer title
remainderMinMaxScaler
columntransfittransformX 2
```

```
array1 05
0 1
05 05
1 0
```

```
Themakecolumntransformer function is available to more easily create a ColumnTransformer object
Specifically the names will be given automatically The equivalent for the above example would be
from sklearncompose import makecolumntransformer
columntrans makecolumntransformer
```

```
OneHotEncoder city
CountVectorizer title
remainderMinMaxScaler
columntrans
ColumnTransformernjobsNone remainderMinMaxScalercopyTrue
sparseshreshold03
transformerweightsNone
transformersonehotencoder
```

- Examples
- Column Transformer with Heterogeneous Data Sources
 - Column Transformer with Mixed Types

352 Feature extraction

The sklearnfeatureextraction module can be used to extract features in a format supported by machine learning algorithms from datasets consisting of formats such as text and image

Note Feature extraction is very different from Feature selection the former consists in transforming arbitrary data such as text or images into numerical features usable for machine learning The latter is a machine learning technique

35 Dataset transformations 583

scikitlearn user guide Release 0213
applied on these features
Loading features from dicts
The classDictVectorizer can be used to convert feature arrays represented as lists of standard Python dict objects to the NumPySciPy representation used by scikitlearn estimators
While not particularly fast to process Python’s dict has the advantages of being convenient to use being sparse
absent features need not be stored and storing feature names in addition to values
DictVectorizer implements what is called oneofK or “onehot” coding for categorical aka nominal discrete features Categorical features are “attributevalue” pairs where the value is restricted to a list of discrete of possibilities without ordering eg topic identifiers types of objects tags names
In the following “city” is a categorical attribute while “temperature” is a traditional numerical feature measurements
city Dubai temperature 33
city London temperature 12
city San Francisco temperature 18

```
from sklearn.feature_extraction import DictVectorizer
vec = DictVectorizer
vec.fit_transform(measurements_to_array)
array 1 0 0 33
0 1 0 12
0 0 1 18
vec.get_feature_names
cityDubai cityLondon citySan Francisco temperature
```

DictVectorizer is also a useful representation transformation for training sequence classifiers in Natural Language Processing models that typically work by extracting feature windows around a particular word of interest
For example suppose that we have a first algorithm that extracts Part of Speech PoS tags that we want to use as complementary tags for training a sequence classifier eg a chunker The following dict could be such a window of features extracted around the word ‘sat’ in the sentence ‘The cat sat on the mat’

```
poswindow

word2 the
pos2 DT
word1 cat
pos1 NN
word1 on
pos1 PP
```

in a real application one would extract many such dictionaries

This description can be vectorized into a sparse twodimensional matrix suitable for feeding into a classifier maybe after being piped into a textTfidfTransformer for normalization

```
vec = DictVectorizer
posvectorized = vec.fit_transform(poswindow)
```

584 Chapter 3 User Guide

scikitlearn user guide Release 0213

```
posvectorized
1x6 sparse matrix of type numpyfloat64
with 6 stored elements in Compressed Sparse format
posvectorizedtoarray
array1 1 1 1 1 1
vecgetfeaturenames
pos1PP pos1NN pos2DT word1on word1cat word2the
```

As you can imagine if one extracts such a context around each individual word of a corpus of documents the resulting matrix will be very wide many onehotfeatures with most of them being valued to zero most of the time So as to make the resulting data structure able to fit in memory the DictVectorizer class uses a scipysparse matrix by default instead of a numpyndarray

Feature hashing

The classFeatureHasher is a highspeed lowmemory vectorizer that uses a technique known as feature hashing or the “hashing trick” Instead of building a hash table of the features encountered in training as the vectorizers do instances of FeatureHasher apply a hash function to the features to determine their column index in sample matrices directly The result is increased speed and reduced memory usage at the expense of inspectability the hasher does not remember what the input features looked like and has no inversetransform method

Since the hash function might cause collisions between unrelated features a signed hash function is used and the sign of the hash value determines the sign of the value stored in the output matrix for a feature This way collisions are likely to cancel out rather than accumulate error and the expected mean of any output feature’s value is zero

This mechanism is enabled by default with alternatesignTrue and is particularly useful for small hash table sizes nfeatures 10000 For large hash table sizes it can be disabled to allow the output to be passed to estimators like sklearnnaivebayesMultinomialNB orsklearnfeatureselectionchi2

feature selectors that expect nonnegative inputs

FeatureHasher accepts either mappings like Python’s dict and its variants in the collections module

feature value pairs or strings depending on the constructor parameter inputtype Mapping are treated as lists offeature value pairs while single strings have an implicit value of 1 so feat1 feat2 feat3 is interpreted as feat1 1 feat2 1 feat3 1 If a single feature occurs multiple times in a sample the associated values will be summed so feat 2 andfeat 35 become feat 55 The output from FeatureHasher is always a scipysparse matrix in the CSR (Compressed Sparse Row) format

Feature hashing can be employed in document classification but unlike textCountVectorizer

FeatureHasher does not do word splitting or any other preprocessing except UnicodetoUTF8 encoding see

Vectorizing a large text corpus with the hashing trick below for a combined tokenizerhasher

As an example consider a wordlevel natural language processing task that needs features extracted from token partofspeech pairs One could use a Python generator function to extract features

```
deftokenfeaturestoken partofspeech
iftokenisdigit
yieldnumeric
else
yieldtokenformattokenlower
yieldtokenpos formattoken partofspeech
iftoken0isupper
yielduppercaseinitial
iftokenisupper
yieldalluppercase
yieldposformatpartofspeech
```

Then therawX to be fed to FeatureHashertransform can be constructed using

35 Dataset transformations 585

scikitlearn user guide Release 0213

rawX tokenfeaturestok postaggertok fortokincorpus

and fed to a hasher with

hasher FeatureHasherinputtypestring

X hashertransformrawX

to get asciipysparse matrixX

Note the use of a generator comprehension which introduces laziness into the feature extraction tokens are only

processed on demand from the hasher

Implementation details

FeatureHasher uses the signed 32bit variant of MurmurHash3 As a result and because of limitations in scipy

sparse the maximum number of features supported is currently 231–1

The original formulation of the hashing trick by Weinberger et al used two separate hash functions *hand* to deter

mine the column index and sign of a feature respectively The present implementation works under the assumption

that the sign bit of MurmurHash3 is independent of its other bits

Since a simple modulo is used to transform the hash function to a column index it is advisable to use a power of two

as thenfeatures parameter otherwise the features will not be mapped evenly to the columns

Text feature extraction

The Bag of Words representation

Text Analysis is a major application field for machine learning algorithms However the raw data a sequence of

symbols cannot be fed directly to the algorithms themselves as most of them expect numerical feature vectors with a

fixed size rather than the raw text documents with variable length

In order to address this scikitlearn provides utilities for the most common ways to extract numerical features from

text content namely

•tokenizing strings and giving an integer id for each possible token for instance by using whitespaces and

punctuation as token separators

•counting the occurrences of tokens in each document

•normalizing and weighting with diminishing importance tokens that occur in the majority of samples documents

In this scheme features and samples are defined as follows

• each individual token occurrence frequency normalized or not is treated as a feature

• the vector of all the token frequencies for a given document is considered a multivariate sample

586 Chapter 3 User Guide

scikitlearn user guide Release 0213

A corpus of documents can thus be represented by a matrix with one row per document and one column per token eg word occurring in the corpus

We call vectorization the general process of turning a collection of text documents into numerical feature vectors This specific strategy tokenization counting and normalization is called the Bag of Words or “Bag of ngrams” representation Documents are described by word occurrences while completely ignoring the relative position information of the words in the document

Sparsity

As most documents will typically use a very small subset of the words used in the corpus the resulting matrix will have many feature values that are zeros typically more than 99 of them

For instance a collection of 10000 short text documents such as emails will use a vocabulary with a size in the order of 100000 unique words in total while each document will use 100 to 1000 unique words individually

In order to be able to store such a matrix in memory but also to speed up algebraic operations matrix vector implementations will typically use a sparse representation such as the implementations available in the scipysparse package

Common Vectorizer usage

CountVectorizer implements both tokenization and occurrence counting in a single class

from sklearn.feature_extraction.text import CountVectorizer

This model has many parameters however the default values are quite reasonable please see the reference documentation for the details

vectorizer = CountVectorizer

vectorizer

CountVectorizer(analyzer='word', binary=False, decode_error='strict',

dtype=np.int64, encoding='utf-8', input_content

lowercase=True, max_df=10, max_features=None, min_df=1,

ngram_range=(1, 1), preprocessor=None, stopwords=None,

strip_accents=None, token_pattern=r'\b\w+\b',

tokenizer=None, vocabulary=None)

Let’s use it to tokenize and count the word occurrences of a minimalistic corpus of text documents

corpus

This is the first document

This is the second second document

And the third one

Is this the first document

X = vectorizer.fit_transform(corpus)

X

4x9 sparse matrix of type np.int64

with 19 stored elements in Compressed Sparse format

The default configuration tokenizes the string by extracting words of at least 2 letters The specific function that does this step can be requested explicitly

35 Dataset transformations 587

scikitlearn user guide Release 0213

```
analyze vectorizerbuildanalyzer
analyzeThis is a text document to analyze
this is text document to analyze
```

Using stop words

Stop words are words like “and” “the” “him” which are presumed to be uninformative in representing the content of a text and which may be removed to avoid them being construed as signal for prediction Sometimes however similar words are useful for prediction such as in classifying writing style or personality

There are several known issues in our provided ‘english’ stop word list See NQY18

Please take care in choosing a stop word list Popular stop word lists may include words that are highly informative to some tasks such as computer

You should also make sure that the stop word list has had the same preprocessing and tokenization applied as the one used in the vectorizer The word we’ve is split into weandveby CountVectorizer’s default tokenizer so if we’ve is in stopwords but veis not vewill be retained from we’ve in transformed text Our vectorizers will try to identify and warn about some kinds of inconsistencies

References

Tf-idf term weighting

In a large text corpus some words will be very present eg “the” “a” “is” in English hence carrying very little meaningful information about the actual contents of the document If we were to feed the direct count data directly to a classifier those very frequent terms would shadow the frequencies of rarer yet more interesting terms In order to reweight the count features into floating point values suitable for usage by a classifier it is very common to use the tf-idf transform

Tf means termfrequency while tf-idf means termfrequency times inverse documentfrequency $tfd = tf \times idf$

$tfd \times idf$

Using the TfidfTransformer’s default settings TfidfTransformernorml2 useidfTrue

smoothidfTrue sublineartfFalse the term frequency the number of times a term occurs in a given document is multiplied with idf component which is computed as

$idf = \log \frac{1}{p}$

$idf = 1$

where p is the total number of documents in the document set and d is the number of documents in the document set that contain term t The resulting tfidf vectors are then normalized by the Euclidean norm

$\frac{1}{\sqrt{\sum_i tfidf_i^2}}$

$\frac{1}{\sqrt{2}}$

$\frac{1}{\sqrt{2}}$

This was originally a term weighting scheme developed for information retrieval as a ranking function for search engines results that has also found good use in document classification and clustering

The following sections contain further explanations and examples that illustrate how the tfidfs are computed exactly and how the tfidfs computed in scikitlearn’s TfidfTransformer andTfidfVectorizer differ slightly from the standard textbook notation that defines the idf as

$idf = \log \frac{1}{p}$

$idf = 1$

In theTfidfTransformer andTfidfVectorizer withsmoothidfFalse the “1” count is added to the idf instead of the idf’s denominator

$idf = \log \frac{1}{p+1}$

$idf = 1$

scikitlearn user guide Release 0213

This normalization is implemented by the TfidfTransformer class

```
from sklearn.feature_extraction.text import TfidfTransformer
```

```
transformer = TfidfTransformer(smooth_idf=False)
```

```
transformer
```

```
TfidfTransformer(norml2=True, smooth_idf=False, sublinear_tf=False)
```

```
use_idf=True
```

Again please see the reference documentation for the details on all the parameters

Let's take an example with the following counts The first term is present 100 of the time hence not very interesting

The two other features only in less than 50 of the time hence probably more representative of the content of the documents

```
counts = [[3, 0, 1]
```

```
          [2, 0, 0]
```

```
          [3, 0, 0]
```

```
          [4, 0, 0]
```

```
          [3, 2, 0]
```

```
          [3, 0, 2]]
```

```
tfidf = transformer.fit_transform(counts)
```

```
tfidf
```

```
6x3 sparse matrix of type numpy.float64
```

```
with 9 stored elements in Compressed Sparse format
```

```
tfidf.toarray()
```

```
array([[0.81940995, 0.057320793,
```

```
       [1.0, 0.0,
```

```
       [1.0, 0.0,
```

```
       [1.0, 0.0,
```

```
       [0.47330339, 0.088089948, 0.
```

```
       [0.58149261, 0.081355169,
```

```
       [0.58149261, 0.081355169,
```

```
       [0.58149261, 0.081355169,
```

```
       [0.58149261, 0.081355169,
```

For example we can compute the tfidf of the first term in the first document in the counts array as follows

```
df[0,0]
```

```
df[0,0] = 3
```

```
idf[0,0] = log
```

```
df[0,0] = 1 + log(3) = 1.1
```

```
tfidf[0,0] = df[0,0] * idf[0,0] = 3 * 1.1 = 3.3
```

Now if we repeat this computation for the remaining 2 terms in the document we get

```
tfidf[0,1] = 0 * log(6) = 0
```

```
tfidf[0,2] = 1 * log(2) = 1 * 0.693 = 0.693
```

and the vector of raw tfidfs

```
tfidf[0,:] = [3.3, 0, 0.693]
```

Then applying the Euclidean L2 norm we obtain the following tfidfs for document 1

```
3.3^2 + 0^2 + 0.693^2
```

```
3.3^2 + 0^2 + 0.693^2 = 11.1801
```

```
sqrt(11.1801) = 3.3436
```

590 Chapter 3 User Guide

scikitlearn user guide Release 0213

Furthermore the default parameter smoothidfTrue adds “1” to the numerator and denominator as if an extra document was seen containing every term in the collection exactly once which prevents zero divisions

idf= log1=

1df= 1

Using this modification the tfidf of the third term in document 1 changes to 18473

tfidf term3 1×log73 1≈18473

And the L2normalized tfidf changes to

The weights of each feature computed by the fit method call are stored in a model attribute

transformeridf

array1 225 184

As tf-idf is very often used for text features there is also another class called TfIdfVectorizer that combines all

the options of CountVectorizer andTfidfTransformer in a single model

from sklearnfeatureextractiontext import TfIdfVectorizer

vectorizer TfIdfVectorizer

vectorizerfittransformcorpus

4x9 sparse matrix of type numpyfloat64

with 19 stored elements in Compressed Sparse format

While the tf-idf normalization is often very useful there might be cases where the binary occurrence markers might

offer better features This can be achieved by using the binary parameter of CountVectorizer In particular

some estimators such as Bernoulli Naive Bayes explicitly model discrete boolean random variables Also very short

texts are likely to have noisy tf-idf values while the binary occurrence info is more stable

As usual the best way to adjust the feature extraction parameters is to use a crossvalidated grid search for instance by

pipelining the feature extractor with a classifier

•Sample pipeline for text feature extraction and evaluation

Decoding text files

Text is made of characters but files are made of bytes These bytes represent characters according to some encoding

To work with text files in Python their bytes must be decoded to a character set called Unicode Common encodings

are ASCII Latin1 Western Europe KOI8R Russian and the universal encodings UTF8 and UTF16 Many

others exist

Note An encoding can also be called a ‘character set’ but this term is less accurate several encodings can exist for

a single character set

35 Dataset transformations 591

scikitlearn user guide Release 0213

The text feature extractors in scikitlearn know how to decode text files but only if you tell them what encoding the files are in The CountVectorizer takes anencoding parameter for this purpose For modern text files the correct encoding is probably UTF8 which is therefore the default encodingutf8

If the text you are loading is not actually encoded with UTF8 however you will get a UnicodeDecodeError

The vectorizers can be told to be silent about decoding errors by setting the decodeerror parameter to either ignore orreplace See the documentation for the Python function bytesdecode for more details type helpbytesdecode at the Python prompt

If you are having trouble decoding text here are some things to try

- Find out what the actual encoding of the text is The file might come with a header or README that tells you the encoding or there might be some standard encoding you can assume based on where the text comes from

- You may be able to find out what kind of encoding it is in general using the UNIX command file The Python chardet module comes with a script called chardetectpy that will guess the specific encoding though you cannot rely on its guess being correct

- You could try UTF8 and disregard the errors You can decode byte strings with bytes decodeerrorsreplace to replace all decoding errors with a meaningless character or set decodeerrorreplace in the vectorizer This may damage the usefulness of your features

- Real text may come from a variety of sources that may have used different encodings or even be sloppily decoded in a different encoding than the one it was encoded with This is common in text retrieved from the Web The Python package ftfy can automatically sort out some classes of decoding errors so you could try decoding the unknown text as latin1 and then using ftfy to fix errors

- If the text is in a mishmash of encodings that is simply too hard to sort out which is the case for the 20 Newsgroups dataset you can fall back on a simple singlebyte encoding such as latin1 Some text may display incorrectly but at least the same sequence of bytes will always represent the same feature

For example the following snippet uses chardet not shipped with scikitlearn must be installed separately to figure out the encoding of three texts It then vectorizes the texts and prints the learned vocabulary The output is not shown here

```
import chardet
text1 bSei mir gegr xc3xbxc3x9f t mein Sauerkraut
text2 bholdselig sind deine Ger xfcche
text3 b xffxfe Ax00ux00fx00 x00 Fx00lx00xfcx00 gx00ex00lx00nx00
↵x00dx00ex00sx00 x00 Gx00ex00sx00ax00nx00gx00ex00sx00x00
↵x00Hx00ex00rx00zx00lx00ix00ex00bx00cx00hx00ex00nx00x00
↵x00tx00rx00ax00gx00 x00 ix00cx00hx00 x00 dx00ix00cx00hx00
↵x00fx00ox00rx00tx00
decoded xdecodechardetdetectxencoding
for xintext1 text2 text3
v CountVectorizerfitdecodedvocabulary
for terminv printv
```

Depending on the version of chardet it might get the first one wrong

For an introduction to Unicode and character encodings in general see Joel Spolsky’s Absolute Minimum Every Software Developer Must Know About Unicode

Applications and examples

The bag of words representation is quite simplistic but surprisingly useful in practice

In particular in a supervised setting it can be successfully combined with fast and scalable linear models to train document classifiers for instance

scikitlearn user guide Release 0213

•Classification of text documents using sparse features

In an unsupervised setting it can be used to group similar documents together by applying clustering algorithms such asKmeans

•Clustering text documents using kmeans

Finally it is possible to discover the main topics of a corpus by relaxing the hard assignment constraint of clustering for instance by using Nonnegative matrix factorization NMF (Non-Negative Matrix Factorization) or NNMF

•Topic extraction with Nonnegative Matrix Factorization and Latent Dirichlet Allocation

Limitations of the Bag of Words representation

A collection of unigrams what bag of words is cannot capture phrases and multiword expressions effectively disregarding any word order dependence Additionally the bag of words model doesn't account for potential misspellings or word derivations

Ngrams to the rescue Instead of building a simple collection of unigrams n1 one might prefer a collection of bigrams n2 where occurrences of pairs of consecutive words are counted

One might alternatively consider a collection of character ngrams a representation resilient against misspellings and derivations

For example let's say we're dealing with a corpus of two documents words wprds The second document contains a misspelling of the word 'words' A simple bag of words representation would consider these two as very distinct documents differing in both of the two possible features A character 2gram representation however would find the documents matching in 4 out of 8 features which may help the preferred classifier decide better ngramvectorizer CountVectorizeranalyzercharwb ngramrange2 2

35 Dataset transformations 593

scikitlearn user guide Release 0213

The word boundariesaware variant charwb is especially interesting for languages that use whitespaces for word separation as it generates significantly less noisy features than the raw char variant in that case For such languages it can increase both the predictive accuracy and convergence speed of classifiers trained using such features while retaining the robustness with regards to misspellings and word derivations While some local positioning information can be preserved by extracting ngrams instead of individual words bag of words and bag of ngrams destroy most of the inner structure of the document and hence most of the meaning carried by that internal structure

In order to address the wider task of Natural Language Understanding the local structure of sentences and paragraphs should thus be taken into account Many such models will thus be casted as “Structured output” problems which are currently outside of the scope of scikitlearn

Vectorizing a large text corpus with the hashing trick

The above vectorization scheme is simple but the fact that it holds an in memory mapping from the string tokens to the integer feature indices thevocabulary attribute causes several problems when dealing with large datasets

- the larger the corpus the larger the vocabulary will grow and hence the memory use too
- fitting requires the allocation of intermediate data structures of size proportional to that of the original dataset
- building the wordmapping requires a full pass over the dataset hence it is not possible to fit text classifiers in a strictly online manner
- pickling and unpickling vectorizers with a large vocabulary can be very slow typically much slower than pickling unpickling flat data structures such as a NumPy array of the same size
- it is not easily possible to split the vectorization work into concurrent sub tasks as the vocabulary attribute would have to be a shared state with a fine grained synchronization barrier the mapping from token string to feature index is dependent on ordering of the first occurrence of each token hence would have to be shared potentially harming the concurrent workers’ performance to the point of making them slower than the sequential variant

It is possible to overcome those limitations by combining the “hashing trick” Feature hashing implemented by the sklearnfeatureextractionFeatureHasher class and the text preprocessing and tokenization features of theCountVectorizer

This combination is implementing in HashingVectorizer a transformer class that is mostly API (Application Programming Interface) compatible with CountVectorizer HashingVectorizer is stateless meaning that you don’t have to call fit on it

from sklearnfeatureextractiontext import HashingVectorizer

hv = HashingVectorizer(nfeatures=10

hvtransformcorpus

4x10 sparse matrix of type numpyfloat64

with 16 stored elements in Compressed Sparse format

You can see that 16 nonzero feature tokens were extracted in the vector output this is less than the 19 nonzeros extracted previously by the CountVectorizer on the same toy corpus The discrepancy comes from hash function collisions because of the low value of the nfeatures parameter

In a real world setting the nfeatures parameter can be left to its default value of 220roughly one million possible features If memory or downstream models size is an issue selecting a lower value such as 218might help without introducing too many additional collisions on typical text classification tasks

scikitlearn user guide Release 0213

Note that the dimensionality does not affect the CPU training time of algorithms which operate on CSR (Compressed Sparse Row) matrices LinearSVCdualTrue Perceptron SGDClassifier PassiveAggressive but it does for algorithms that work with CSC matrices LinearSVCdualFalse Lasso etc

Let's try again with the default setting

```
hv = HashingVectorizer  
hv.transform(corpus
```

4x1048576 sparse matrix of type numpyfloat64
with 19 stored elements in Compressed Sparse format

We no longer get the collisions but this comes at the expense of a much larger dimensionality of the output space Of course other terms than the 19 used here might still collide with each other

TheHashingVectorizer also comes with the following limitations

- it is not possible to invert the model no inversetransform method nor to access the original string representation of the features because of the oneway nature of the hash function that performs the mapping
- it does not provide IDF weighting as that would introduce statefulness in the model A TfidfTransformer can be appended to it in a pipeline if required

Performing outofcore scaling with HashingVectorizer

An interesting development of using a HashingVectorizer is the ability to perform outofcore scaling This means that we can learn from data that does not fit into the computer's main memory

A strategy to implement outofcore scaling is to stream data to the estimator in minibatches Each minibatch is vectorized using HashingVectorizer so as to guarantee that the input space of the estimator has always the same dimensionality The amount of memory used at any time is thus bounded by the size of a minibatch Although there is no limit to the amount of data that can be ingested using such an approach from a practical point of view the learning time is often limited by the CPU time one wants to spend on the task

For a fullfledged example of outofcore scaling in a text classification task see Outofcore classification of text documents

Customizing the vectorizer classes

It is possible to customize the behavior by passing a callable to the vectorizer constructor

```
def mytokenizers  
    return ssplit
```

```
vectorizer = CountVectorizertokenizermymtokenizer  
vectorizer.buildanalyzer(some_punctuation  
    some_punctuation  
    True
```

In particular we name

- preprocessor a callable that takes an entire document as input as a single string and returns a possibly transformed version of the document still as an entire string This can be used to remove HTML tags lowercase the entire document etc
- tokenizer a callable that takes the output from the preprocessor and splits it into tokens then returns a list of these

35 Dataset transformations 595

scikitlearn user guide Release 0213

•analyzer a callable that replaces the preprocessor and tokenizer The default analyzers all call the preprocessor and tokenizer but custom analyzers will skip this Ngram extraction and stop word filtering take place at the analyzer level so a custom analyzer may have to reproduce these steps
Lucene users might recognize these names but be aware that scikitlearn concepts may not map onetooone onto Lucene concepts

To make the preprocessor tokenizer and analyzers aware of the model parameters it is possible to derive from the class and override the buildpreprocessor buildtokenizer andbuildanalyzer factory methods instead of passing custom functions

Some tips and tricks

• If documents are pretokenized by an external package then store them in files or strings with the tokens separated by whitespace and pass analyzerstrsplit
• Fancy tokenlevel analysis such as stemming lemmatizing compound splitting filtering based on partof speech etc are not included in the scikitlearn codebase but can be added by customizing either the tokenizer or the analyzer Here’s a CountVectorizer with a tokenizer and lemmatizer using NLTK

```
from nltk import wordtokenize
from nltkstem import WordNetLemmatizer
class LemmaTokenizer object
def initself
selfwnl WordNetLemmatizer
def callself doc
return selfwnllemmatizet fortinwordtokenizedoc
```

vect CountVectorizertokenizerLemmaTokenizer

Note that this will not filter out punctuation

The following example will for instance transform some British spelling to American spelling

```
import re
def tobritishtokens
for tintokens
t resubrou r1or t
t resubrbtre r1er t
t resubriyseingation r1z2 t
t resubrogue og t
yield t
```

```
class CustomVectorizer CountVectorizer
def buildtokenizerself
tokenize superbuilttokenizer
return lambda doc listtobritishtokenizedoc
```

```
printCustomVectorizerbuildanalyzerucolor colour
color color
```

for other styles of preprocessing examples include stemming lemmatization or normalizing numerical tokens with the latter illustrated in

-Biclustering documents with the Spectral Coclustering algorithm

Customizing the vectorizer can also be useful when handling Asian languages that do not use an explicit word separator such as whitespace

scikitlearn user guide Release 0213

Image feature extraction

Patch extraction

Theextractpatches2d function extracts patches from an image stored as a twodimensional array or threedimensional with color information along the third axis For rebuilding an image from all its patches use reconstructfrompatches2d For example let use generate a 4x4 pixel picture with 3 color channels eg in RGB format

```
import numpy as np
from sklearnfeatureextraction import image
oneimage = np.arange(4 * 4 * 3).reshape(4, 4, 3)
oneimage[0, 0, 0] = 12 # R channel of a fake RGB picture
oneimage[0, 0, 1] = 15
oneimage[0, 0, 2] = 18
oneimage[0, 1, 0] = 24
oneimage[0, 1, 1] = 27
oneimage[0, 1, 2] = 30
oneimage[0, 2, 0] = 36
oneimage[0, 2, 1] = 39
oneimage[0, 2, 2] = 42
oneimage[0, 3, 0] = 45
patches = imageextractpatches2d(oneimage, 2, 2, max_patches=20,
                                random_state=0)
patches.shape
(2, 2, 2, 3)
patches[0, 0, 0, 0]
array([0, 3])
patches[0, 0, 0, 1]
array([12, 15])
patches[0, 0, 0, 2]
array([18, 27])
patches[0, 0, 1, 0]
array([15, 24])
patches[0, 0, 1, 1]
array([27, 30])
patches[0, 0, 2, 0]
array([36, 45])
patches[0, 0, 2, 1]
array([42, 45])
```

Let us now try to reconstruct the original image from the patches by averaging on overlapping areas

reconstructed = image_reconstruct_from_patches_2d(patches, 4, 4, 3)

np.testing.assert_array_equal(oneimage, reconstructed)

ThePatchExtractor class works in the same way as extractpatches2d only it supports multiple images as input It is implemented as an estimator so it can be used in pipelines See

```
five_images = np.arange(5 * 4 * 4 * 3).reshape(5, 4, 4, 3)
patches = imagePatchExtractor(2, 2).transform(five_images)
patches.shape
(4, 5, 2, 2, 3)
```

Connectivity graph of an image

Several estimators in the scikitlearn can use connectivity information between features or samples For instance Ward clustering Hierarchical clustering can cluster together only neighboring pixels of an image thus forming contiguous patches

For this purpose the estimators use a 'connectivity' matrix giving which samples are connected

scikitlearn user guide Release 0213

The function `imgtograph` returns such a matrix from a 2D or 3D image. Similarly `gridtograph` build a connectivity matrix for images given the shape of these image

These matrices can be used to impose connectivity in estimators that use connectivity information such as Ward clustering. Hierarchical clustering, but also to build precomputed kernels or similarity matrices

Note Examples

- A demo of structured Ward hierarchical clustering on an image of coins
- Spectral clustering for image segmentation
- Feature agglomeration vs univariate selection

353 Preprocessing data

The `sklearn.preprocessing` package provides several common utility functions and transformer classes to change raw feature vectors into a representation that is more suitable for the downstream estimators

In general learning algorithms benefit from standardization of the data set. If some outliers are present in the set, robust scalers or transformers are more appropriate. The behaviors of the different scalers, transformers, and normalizers on

a dataset containing marginal outliers is highlighted in `Compare the effect of different scalers on data with outliers`. Standardization or mean removal and variance scaling

Standardization of datasets is a common requirement for many machine learning estimators implemented in `scikitlearn`. They might behave badly if the individual features do not more or less look like standard normally distributed data: Gaussian with zero mean and unit variance

In practice, we often ignore the shape of the distribution and just transform the data to center it by removing the mean value of each feature, then scale it by dividing nonconstant features by their standard deviation

For instance, many elements used in the objective function of a learning algorithm, such as the RBF (Radial Basis Function) kernel of Support Vector Machines or the $L1$ and $L2$ regularizers of linear models, assume that all features are centered around zero and

have variance in the same order. If a feature has a variance that is orders of magnitude larger than others, it might dominate the objective function and make the estimator unable to learn from other features correctly as expected

The function `scale` provides a quick and easy way to perform this operation on a single arraylike dataset

```
from sklearn import preprocessing
```

```
import numpy as np
```

It is possible to disable either centering or scaling by either passing withmean False or withstd False to
the constructor of StandardScaler

Scaling features to a range

An alternative standardization is scaling features to lie between a given minimum and maximum value often between
zero and one or so that the maximum absolute value of each feature is scaled to unit size This can be achieved using
MinMaxScaler or MaxAbsScaler respectively

The motivation to use this scaling include robustness to very small standard deviations of features and preserving zero
entries in sparse data

Here is an example to scale a toy data matrix to the 0 1 range

35 Dataset transformations 599

scikitlearn user guide Release 0213

As withscale the module further provides convenience functions minmaxscale andmaxabsscale if you don't want to create an object

Scaling sparse data

Centering sparse data would destroy the sparseness structure in the data and thus rarely is a sensible thing to do However it can make sense to scale sparse inputs especially if features are on different scales

MaxAbsScaler andmaxabsscale were specifically designed for scaling sparse data and are the recommended way to go about this However scale andStandardScaler can accept scipysparse matrices as input as long aswithmeanFalse is explicitly passed to the constructor Otherwise a ValueError will be raised as silently centering would break the sparsity and would often crash the execution by allocating excessive amounts of memory unintentionally RobustScaler cannot be fitted to sparse inputs but you can use the transform method on sparse inputs

Note that the scalers accept both Compressed Sparse Rows and Compressed Sparse Columns format see scipy sparsecsrmatrix andscipysparsecsrmatrix Any other sparse input will be converted to the Compressed Sparse Rows representation To avoid unnecessary memory copies it is recommended to choose the CSR (Compressed Sparse Row) or CSC representation upstream

Finally if the centered data is expected to be small enough explicitly converting the input to an array using the toarray method of sparse matrices is another option

Scaling data with outliers

If your data contains many outliers scaling using the mean and variance of the data is likely to not work very well In these cases you can use robustscale andRobustScaler as dropin replacements instead They use more robust estimates for the center and range of your data

References

Further discussion on the importance of centering and scaling data is available on this FAQ Should I normalize and rescale the data

Scaling vs Whitening

It is sometimes not enough to center and scale the features independently since a downstream model can further make some assumption on the linear independence of the features

To address this issue you can use sklearn.decomposition.PCA withwhitenTrue to further remove the linear correlation across features

Scaling a 1D array

All above functions ie scale minmaxscale maxabsscale androbustscale accept 1D array which can be useful in some specific case

35 Dataset transformations 601

Centering kernel matrices

If you have a kernel matrix of a kernel κ that computes a dot product in a feature space defined by function ϕ h a `KernelCenterer` can transform the kernel matrix so that it contains inner products in the feature space defined by ϕ h followed by removal of the mean in that space

Nonlinear transformation

Two types of transformations are available quantile transforms and power transforms Both quantile and power transforms are based on monotonic transformations of the features and thus preserve the rank of the values along each feature

Quantile transforms put all features into the same desired distribution based on the formula $\Phi^{-1}(\frac{i}{n+1})$ where Φ is the cumulative distribution function of the feature and Φ^{-1} the quantile function of the desired output distribution Φ This formula is using the two following facts i if Φ is a random variable with a continuous cumulative distribution function Φ then $\Phi(\Phi^{-1}(u))$ is uniformly distributed on $[0, 1]$ ii if Φ is a random variable with uniform distribution on $[0, 1]$ then $\Phi^{-1}(\Phi)$ has distribution Φ By performing a rank transformation a quantile transform smooths out unusual distributions and is less influenced by outliers than scaling methods It does however distort correlations and distances within and across features

Power transforms are a family of parametric transformations that aim to map data from any distribution to as close to a Gaussian distribution

Mapping to a Uniform distribution

`QuantileTransformer` and `quantiletransform` provide a nonparametric transformation to map the data to a uniform distribution with values between 0 and 1

```
from sklearn.datasets import loadiris
from sklearn.model_selection import train_test_split
iris = loadiris
X, y = iris.data, iris.target
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
quantile_transformer = preprocessing.QuantileTransformer(random_state=0)
X_train_trans = quantile_transformer.fit_transform(X_train)
X_test_trans = quantile_transformer.transform(X_test)
np.percentile(X_train, 0, 25, 50, 75, 100)
array(43. 51. 58. 65. 79.)
```

This feature corresponds to the sepal length in cm Once the quantile transformation applied those landmarks approach closely the percentiles previously defined

```
np.percentile(X_train_trans, 0, 25, 50, 75, 100)
array(0.00 0.24 0.49 0.73 0.99)
This can be confirmed on a independent testing set with similar remarks
np.percentile(X_test, 0, 25, 50, 75, 100)
array(44. 51.25 57.5 61.75 73.)
np.percentile(X_test_trans, 0, 25, 50, 75, 100)
```

Mapping to a Gaussian distribution

In many modeling scenarios normality of the features in a dataset is desirable Power transforms are a family of parametric monotonic transformations that aim to map data from any distribution to as close to a Gaussian distribution as possible in order to stabilize variance and minimize skewness

PowerTransformer currently provides two such power transformations the YeoJohnson transform and the BoxCox transform

The YeoJohnson transform is given by

$$\lambda = \begin{cases} \lambda & \text{if } x \geq 0 \\ 1 - \lambda & \text{if } x < 0 \end{cases}$$
$$\ln \left(\lambda x + 1 \right) \text{ if } x \geq 0$$
$$-\ln \left(-\lambda x + 1 \right) \text{ if } x < 0$$

while the BoxCox transform is given by

$$\lambda = \begin{cases} \lambda & \text{if } x \geq 0 \\ -\lambda & \text{if } x < 0 \end{cases}$$
$$\ln \left(\lambda x + 1 \right) \text{ if } x \geq 0$$
$$\ln \left(-\lambda x + 1 \right) \text{ if } x < 0$$

BoxCox can only be applied to strictly positive data In both methods the transformation is parameterized by λ which is determined through maximum likelihood estimation Here is an example of using BoxCox to map samples drawn from a lognormal distribution to a normal distribution

```
pt = preprocessing.PowerTransformer(method='boxcox', standardize=False)
Xlognormal = np.random.RandomState(616).lognormal(size=(3, 3))
Xlognormal
array([[128. 118.  84.],
       [ 94. 160.  38.],
       [135.  21. 109.]])
pt.fit_transform(Xlognormal)
array([[ 49.  17.  15.],
       [  5.  58.  57.],
       [ 69.  84.  10.]])
```

While the above example sets the standardize option to False PowerTransformer will apply zero mean

unit variance normalization to the transformed output by default

Below are examples of BoxCox and YeoJohnson applied to various probability distributions Note that when applied to certain distributions the power transforms achieve very Gaussianlike results but with others they are ineffective This highlights the importance of visualizing the data before and after transformation

It is also possible to map data to a normal distribution using QuantileTransformer by setting

```
output_distribution = 'normal'
qt = preprocessing.QuantileTransformer(
    output_distribution='normal', random_state=0)
Xtrans = qt.fit_transform(X)
Xtrans
array([[ 4.  2.  1.  0.],
       [44. 22. 11.  0.],
       [44. 22. 12.  0.]])
```

77 41 67 25
77 42 67 25
79 44 69 25

Thus the median of the input becomes the mean of the output centered at 0 The normal output is clipped so that the input's minimum and maximum — corresponding to the 1e7 and 1 - 1e7 quantiles respectively — do not become infinite under the transformation

Normalization

Normalization is the process of scaling individual samples to have unit norm This process can be useful if you plan to use a quadratic form such as the dotproduct or any other kernel to quantify the similarity of any pair of samples This assumption is the base of the Vector Space Model often used in text classification and clustering contexts The function normalize provides a quick and easy way to perform this operation on a single arraylike dataset either using the l1orl2norms

```
X = [[1, 1, 2],
     [2, 0, 0],
     [0, 1, 1]]
Xnormalized = preprocessing.normalize(X, norml2)
Xnormalized
array([0.4, 0.4, 0.8],
      [1, 0, 0],
      [0, 0.7, 0.7])
```

The preprocessing module further provides a utility class Normalizer that implements the same operation using the Transformer API (Application Programming Interface) even though the fit method is useless in this case the class is stateless as this operation treats samples independently

This class is hence suitable for use in the early steps of a sklearn pipeline Pipeline

```
normalizer = preprocessing.Normalizer.fit(X) # fit does nothing
normalizer
```

```
Normalizer(copy=True, norml2=1)
```

The normalizer instance can then be used on sample vectors as any transformer

```
normalizer.transform(X)
array([0.4, 0.4, 0.8],
      [1, 0, 0],
      [0, 0.7, 0.7])
normalizer.transform([1, 1, 0])
array([0.7, 0.7, 0])
```

Sparse input

normalize and Normalizer accept both dense arraylike and sparse matrices from scipy sparse as input For sparse input the data is converted to the Compressed Sparse Rows representation see scipy sparse csr matrix before being fed to efficient Cython routines To avoid unnecessary memory copies it is recommended to choose the CSR (Compressed Sparse Row) representation upstream

scikitlearn user guide Release 0213

Encoding categorical features

Often features are not given as continuous values but categorical For example a person could have features male female from Europe from US from Asia uses Firefox uses Chrome uses Safari uses Internet Explorer Such features can be efficiently coded as integers for instance male from US uses Internet Explorer could be expressed as 0 1 3 while female from Asia uses Chrome would be 1 2 1

To convert categorical features to such integer codes we can use the OrdinalEncoder This estimator transforms each categorical feature to one new feature of integers 0 to ncategories - 1

enc_preprocessing.OrdinalEncoder

X = male from US uses Safari female from Europe uses Firefox

↪

enc.fit(X)

OrdinalEncoder(categories=auto dtype = numpy.float64

enc.transform(female from US uses Safari

array([0, 1, 1])

Such integer representation can however not be used directly with all scikitlearn estimators as these expect continuous input and would interpret the categories as being ordered which is often not desired ie the set of browsers was ordered arbitrarily

Another possibility to convert categorical features to features that can be used with scikitlearn estimators is to use a oneofK also known as onehot or dummy encoding This type of encoding can be obtained with the OneHotEncoder which transforms each categorical feature with ncategories possible values into ncategories binary features with one of them 1 and all others 0

Continuing the example above

enc_preprocessing.OneHotEncoder

X = male from US uses Safari female from Europe uses Firefox

↪

enc.fit(X)

OneHotEncoder(categories=None dtype = numpy.float64 handle_unknown = error

nvalues=None sparse=True

enc.transform(female from US uses Safari

male from Europe uses Safari to array

array([[1, 0, 0, 1, 0, 1],

[0, 1, 1, 0, 0, 1]])

By default the values each feature can take is inferred automatically from the dataset and can be found in the categories attribute

enc.categories

array([female, male], dtype=object) array([from Europe, from US],

dtype=object) array([uses Firefox, uses Safari], dtype=object)

It is possible to specify this explicitly using the parameter categories There are two genders four possible

continents and four web browsers in our dataset

genders = female, male

locations = from Africa, from Asia, from Europe, from US

browsers = uses Chrome, uses Firefox, uses IE, uses Safari

enc_preprocessing.OneHotEncoder(categories=genders, locations, browsers)

Note that for there are missing categorical values for the 2nd and 3rd feature

scikitlearn user guide Release 0213

X male from US uses Safari female from Europe uses Firefox

↪

encfitX

OneHotEncodercategoricalfeaturesNone

categories dropNone

dtype numpyfloat64 handleunknownerror

nvaluesNone sparseTrue

enctransformfemale from Asia uses Chrometoarray

array1 0 0 1 0 0 1 0 0 0

If there is a possibility that the training data might have missing categorical features it can often be

better to specify handleunknownignore instead of setting the categories manually as above

Whenhandleunknownignore is specified and unknown categories are encountered during trans

form no error will be raised but the resulting onehot encoded columns for this feature will be all zeros

handleunknownignore is only supported for onehot encoding

enc preprocessingOneHotEncoderhandleunknownignore

X male from US uses Safari female from Europe uses Firefox

↪

encfitX

OneHotEncodercategoricalfeaturesNone categoriesNone dropNone

dtype numpyfloat64 handleunknownignore

nvaluesNone sparseTrue

enctransformfemale from Asia uses Chrometoarray

array1 0 0 0 0 0

It is also possible to encode each column into ncategories 1 columns instead of ncategories columns

by using the drop parameter This parameter allows the user to specify a category for each feature to be dropped This

is useful to avoid colinearity in the input matrix in some classifiers Such functionality is useful for example when

using nonregularized regression LinearRegression since colinearity would cause the covariance matrix to be

noninvertible When this parameter is not None handleunknown must be set to error

SeeLoading features from dicts for categorical features that are represented as a dict not as scalars

Discretization

Discretization otherwise known as quantization or binning provides a way to partition continuous features into dis

crete values Certain datasets with continuous features may benefit from discretization because discretization can

transform the dataset of continuous attributes to one with only nominal attributes

Onehot encoded discretized features can make a model more expressive while maintaining interpretability For

instance preprocessing with a discretizer can introduce nonlinearity to linear models

35 Dataset transformations 607

scikitlearn user guide Release 0213

Kbins discretization

KBinsDiscretizer discretizes features into kbins

X nparray 3 5 15

0 6 14

6 3 11

est preprocessingKBinsDiscretizernbins3 2 2 encodeordinalfitX

By default the output is onehot encoded into a sparse matrix See Encoding categorical features and this can be configured with the encode parameter For each feature the bin edges are computed during fit and together with the number of bins they will define the intervals Therefore for the current example these intervals are defined as

• feature 1 $-\infty-1-122\infty$

• feature 2 $-\infty55\infty$

• feature 3 $-\infty1414\infty$

Based on these bin intervals Xis transformed as follows

esttransformX

array 0 1 1

1 1 1

2 0 0

The resulting dataset contains ordinal attributes which can be further used in a sklearnpipelinePipeline

Discretization is similar to constructing histograms for continuous data However histograms focus on counting features which fall into particular bins whereas discretization focuses on assigning feature values to these bins

KBinsDiscretizer implements different binning strategies which can be selected with the strategy parame

ter The 'uniform' strategy uses constantwidth bins The 'quantile' strategy uses the quantiles values to have equally

populated bins in each feature The 'kmeans' strategy defines bins based on a kmeans clustering procedure performed on each feature independently

Examples

•Using KBinsDiscretizer to discretize continuous features

•Feature discretization

•Demonstrating the different strategies of KBinsDiscretizer

Feature binarization

Feature binarization is the process of thresholding numerical features to get boolean values This can be useful for downstream probabilistic estimators that make assumption that the input data is distributed according to a multivariate Bernoulli distribution For instance this is the case for the sklearnneuralnetworkBernoulliRBM

It is also common among the text processing community to use binary feature values probably to simplify the proba bilistic reasoning even if normalized counts aka term frequencies or TFIDF valued features often perform slightly better in practice

As for the Normalizer the utility class Binarizer is meant to be used in the early stages of sklearn pipelinePipeline Thefit method does nothing as each sample is treated independently of others

608 Chapter 3 User Guide

scikitlearn user guide Release 0213

```

binarizer preprocessingBinarizerfitX fit does nothing
binarizer
BinarizercopyTrue threshold00
binarizertransformX
array1 0 1
1 0 0
0 1 0
```

It is possible to adjust the threshold of the binarizer

```
binarizer preprocessingBinarizerthreshold11
binarizertransformX
array0 0 1
1 0 0
0 0 0
```

As for theStandardScaler andNormalizer classes the preprocessing module provides a companion function

binarize to be used when the transformer API (Application Programming Interface) is not necessary

Note that the Binarizer is similar to the KBinsDiscretizer whenk = 2 and when the bin edge is at the valuethreshold

Sparse input

binarize andBinarizer accept both dense arraylike and sparse matrices from scipysparse as input

For sparse input the data is converted to the Compressed Sparse Rows representation seescipysparse

csrmatrix To avoid unnecessary memory copies it is recommended to choose the CSR (Compressed Sparse Row) representation up stream

Imputation of missing values

Tools for imputing missing values are discussed at Imputation of missing values

Generating polynomial features

Often it's useful to add complexity to the model by considering nonlinear features of the input data A simple and common method to use is polynomial features which can get features' highorder and interaction terms It is implemented

inPolynomialFeatures

```
import numpy as np
from sklearnpreprocessing import PolynomialFeatures
X = np.arange(6).reshape(3, 2)
```

```
X
array0 1
2 3
4 5
poly = PolynomialFeatures2
polyfittransformX

1 6 7 8 42 48 56 336
```

The features of X have been transformed from [1 2 3]to1 [1 2 3] [1]2 [1]3 [2]3 [1]2[3]
Note that polynomial features are used implicitly in kernel methods eg sklearnsvmSVC sklearn
decompositionKernelPCA when using polynomial Kernel functions
SeePolynomial interpolation for Ridge regression using created polynomial features

Custom transformers

Often you will want to convert an existing Python function into a transformer to assist in data cleaning or processing
You can implement a transformer from an arbitrary function with FunctionTransformer For example to build
a transformer that applies a log transformation in a pipeline do

```
import numpy as np
from sklearnpreprocessing import FunctionTransformer
transformer FunctionTransformernplog1p validate True
X nparray0 1 2 3
transformertransformX
array0 069314718
109861229 138629436
```

You can ensure that func andinversefunc are the inverse of each other by setting checkinverseTrue
and calling fit beforetransform Please note that a warning is raised and can be turned into an error with a
filterwarnings

```
import warnings
warningsfilterwarningseerror message checkinverse
categoryUserWarning append False
```

For a full code example that demonstrates using a FunctionTransformer to do custom feature selection see

Using FunctionTransformer to select columns

354 Imputation of missing values

For various reasons many real world datasets contain missing values often encoded as blanks NaNs or other place
holders Such datasets however are incompatible with scikitlearn estimators which assume that all values in an array

scikitlearn user guide Release 0213

are numerical and that all have and hold meaning A basic strategy to use incomplete datasets is to discard entire rows and/or columns containing missing values However this comes at the price of losing data which may be valuable even though incomplete A better strategy is to impute the missing values ie to infer them from the known part of the data See the Glossary of Common Terms and API (Application Programming Interface) Elements entry on imputation

Univariate vs Multivariate Imputation
One type of imputation algorithm is univariate which imputes values in the ith feature dimension using only non missing values in that feature dimension eg `imputeSimpleImputer` By contrast multivariate imputation algorithms use the entire set of available feature dimensions to estimate the missing values eg `imputeIterativeImputer`

Univariate feature imputation

The `SimpleImputer` class provides basic strategies for imputing missing values Missing values can be imputed with a provided constant value or using the statistics mean median or most frequent of each column in which the missing values are located This class also allows for different missing values encodings
The following snippet demonstrates how to replace missing values encoded as `np.nan` using the mean value of the columns axis 0 that contain the missing values

```
import numpy as np
from sklearn.impute import SimpleImputer
imp = SimpleImputer(missing_values=np.nan, strategy='mean')
imp.fit(1 2 np.nan 3 7 6)
SimpleImputer(add_indicator=False, copy=True, fill_value=None,
missing_values=np.nan, strategy='mean', verbose=0)
X = np.nan 2 6 np.nan 7 6
print(imp.transform(X))
4 2
6 3 6 6
7 6
```

The `SimpleImputer` class also supports sparse matrices

```
import scipy.sparse as sp
X = sp.cscmatrix(1 2 0 1 8 4)
imp = SimpleImputer(missing_values=1, strategy='mean')
imp.fit(X)
SimpleImputer(add_indicator=False, copy=True, fill_value=None,
missing_values=1, strategy='mean', verbose=0)
X_test = sp.cscmatrix(1 2 6 1 7 6)
print(imp.transform(X_test).toarray())
3 2
6 3
7 6
```

Note that this format is not meant to be used to implicitly store missing values in the matrix because it would densify it at transform time Missing values encoded by 0 must be used with dense input

The `SimpleImputer` class also supports categorical data represented as string values or pandas categoricals when using the `most_frequent` or `constant` strategy

```
import pandas as pd
df = pd.DataFrame({'x':
np.nan, 'y':
35})
Dataset transformations 611
```

scikitlearn user guide Release 0213

a npnan
b y dtypecategory

imp SimpleImputerstrategymostfrequent
printimpfittransformdf
a x
a y
a y
b y

Multivariate feature imputation

A more sophisticated approach is to use the IterativeImputer class which models each feature with missing values as a function of other features and uses that estimate for imputation It does so in an iterated roundrobin fashion at each step a feature column is designated as output yand the other feature columns are treated as inputs X A regressor is fit on X y for knowny Then the regressor is used to predict the missing values of y This is done for each feature in an iterative fashion and then is repeated for maxiter imputation rounds The results of the final imputation round are returned

Note This estimator is still experimental for now the predictions and the API (Application Programming Interface) might change without any deprecation cycle To use it you need to explicitly import enableiterativeimputer

```
import numpy as np
from sklearn.experimental import enableiterativeimputer
from sklearn.impute import IterativeImputer
imp = IterativeImputer(maxiter=10, random_state=0)
imp.fit(1 2 3 6 4 8 npnan 3 7 npnan)
IterativeImputer(add_indicator=False, estimator=None,
imputation_order='ascending', initial_strategy='mean',
max_iter=10, max_value=None, min_value=None,
missing_values=np.nan, n_nearest_features=None,
random_state=0, sample_posterior=False, tol=0.001,
verbose=0)
X_test = npnan 2 6 npnan npnan 6
# the model learns that the second feature is double the first
print(np.round(imp.transform(X_test), 1))
# 2
# 6 12
# 3 6
```

Both SimpleImputer and IterativeImputer can be used in a Pipeline as a way to build a composite estimator that supports imputation See Imputing missing values before building an estimator
Flexibility of IterativeImputer

There are many well established imputation packages in the R data science ecosystem Amelia mi mice miss Forest etc missForest is popular and turns out to be a particular instance of different sequential imputation algorithms that can all be implemented with IterativeImputer by passing in different regressors to be used for predicting missing feature values In the case of missForest this regressor is a Random Forest See sphxglr/autoexamples/plot_iterative_imputer_variants_comparison.py
612 Chapter 3 User Guide

scikitlearn user guide Release 0213

Multiple vs Single Imputation

In the statistics community it is common practice to perform multiple imputations generating for example mseparate imputations for a single feature matrix Each of these mimputations is then put through the subsequent analysis pipeline eg feature engineering clustering regression classification The mfinal analysis results eg heldout validation errors allow the data scientist to obtain understanding of how analytic results may differ as a consequence of the inherent uncertainty caused by the missing values The above practice is called multiple imputation Our implementation of IterativeImputer was inspired by the R MICE package Multivariate Imputation by Chained Equations¹ but differs from it by returning a single imputation instead of multiple imputations However IterativeImputer can also be used for multiple imputations by applying it repeatedly to the same dataset with different random seeds when sampleposterior=True See² chapter 4 for more discussion on multiple vs single imputations

It is still an open problem as to how useful single vs multiple imputation is in the context of prediction and classification when the user is not interested in measuring uncertainty due to missing values

Note that a call to the transform method ofIterativeImputer is not allowed to change the number of samples Therefore multiple imputations cannot be achieved by a single call to transform

References

Marking imputed values

TheMissingIndicator transformer is useful to transform a dataset into corresponding binary matrix indicating the presence of missing values in the dataset This transformation is useful in conjunction with imputation When using imputation preserving the information about which values had been missing can be informative NaN is usually used as the placeholder for missing values However it enforces the data type to be float The parameter missingvalues allows to specify other placeholder such as integer In the following example we will use 1as missing values

```
from sklearnimpute import MissingIndicator
X = nparray1 1 1 3
  4 1 0 1
  8 1 1 0
indicator = MissingIndicatoremissingvalues1
maskmissingvaluesonly = indicatorfittransformX
maskmissingvaluesonly
array True True False
False True True
False True False
```

Thefeatures parameter is used to choose the features for which the mask is constructed By default it is missingonly which returns the imputer mask of the features containing missing values at fit time indicatorfeatures

```
array0 1 3
Thefeatures parameter can be set to all to returned all features whether or not they contain missing values
indicator = MissingIndicatoremissingvalues1 featuresall
maskall = indicatorfittransformX
```

²Roderick J A Little and Donald B Rubin 1986 “Statistical Analysis with Missing Data” John Wiley Sons Inc New York NY USA
35 Dataset transformations 613

scikitlearn user guide Release 0213

```
maskall
array True True False False
False True False True
False True False False
indicatorfeatures
array0 1 2 3
```

When using the MissingIndicator in aPipeline be sure to use the FeatureUnion or ColumnTransformer to add the indicator features to the regular features First we obtain the iris dataset and add some missing values to it

```
from sklearn.datasets import loadiris
from sklearn.impute import SimpleImputer MissingIndicator
from sklearn.model_selection import train_test_split
from sklearn.pipeline import FeatureUnion make_pipeline
from sklearn.tree import DecisionTreeClassifier
X y = loadiris(return_Xy=True)
mask = np.random.randint(0, 2, size=X.shape[0]).astype(np.bool)
X[mask] = np.nan
X_train X_test y_train y_test = train_test_split(X, y, test_size=100,
                                                    random_state=0)
```

Now we create a FeatureUnion All features will be imputed using SimpleImputer in order to enable classifiers to work with this data Additionally it adds the the indicator variables from MissingIndicator

```
transformer = FeatureUnion(
    transformer_list=[
        features=SimpleImputer(strategy='mean'),
        indicators=MissingIndicator(),
    ])
transformer.fit(X_train, y_train)
results = transformer.transform(X_test)
resultsshape
100 8
```

Of course we cannot use the transformer to make any predictions We should wrap this in a Pipeline with a classifier eg a DecisionTreeClassifier to be able to make predictions

```
clf = make_pipeline(transformer, DecisionTreeClassifier)
clf.fit(X_train, y_train)
results = clf.predict(X_test)
resultsshape
100
```

355 Unsupervised dimensionality reduction

If your number of features is high it may be useful to reduce it with an unsupervised step prior to supervised steps Many of the Unsupervised learning methods implement a transform method that can be used to reduce the dimensionality Below we discuss two specific examples of this pattern that are heavily used

Pipelining
The unsupervised data reduction and the supervised estimator can be chained in one step See Pipeline chaining estimators

scikitlearn user guide Release 0213

PCA (Principal Component Analysis) principal component analysis
decompositionPCA looks for a combination of features that capture well the variance of the original features
SeeDecomposing signals in components matrix factorization problems

Examples

- Faces recognition example using eigenfaces and SVMs

Random projections

The module randomprojection provides several tools for data reduction by random projections See the relevant section of the documentation Random Projection

Examples

- The JohnsonLindenstrauss bound for embedding with random projections

Feature agglomeration

clusterFeatureAgglomeration applies Hierarchical clustering to group together features that behave similarly

Examples

- Feature agglomeration vs univariate selection
- Feature agglomeration

Feature scaling

Note that if features have very different scaling or statistical properties clusterFeatureAgglomeration may not be able to capture the links between related features Using a preprocessingStandardScaler can be useful in these settings

356 Random Projection

Thesklearnrandomprojection module implements a simple and computationally efficient way to reduce the dimensionality of the data by trading a controlled amount of accuracy as additional variance for faster processing times and smaller model sizes This module implements two types of unstructured random matrix Gaussian random matrix andsparse random matrix

The dimensions and distribution of random projections matrices are controlled so as to preserve the pairwise distances between any two samples of the dataset Thus random projection is a suitable approximation technique for distance based method

The JohnsonLindenstrauss lemma

The main theoretical result behind the efficiency of random projection is the JohnsonLindenstrauss lemma quoting Wikipedia

In mathematics the JohnsonLindenstrauss lemma is a result concerning lowdistortion embeddings of points from highdimensional into lowdimensional Euclidean space The lemma states that a small set of points in a highdimensional space can be embedded into a space of much lower dimension in such a way that distances between the points are nearly preserved The map used for the embedding is at least Lipschitz and can even be taken to be an orthogonal projection

Knowing only the number of samples the sklearnrandomprojection

johnsonlindenstraussmindim estimates conservatively the minimal size of the random subspace to guarantee a bounded distortion introduced by the random projection

```
from sklearnrandomprojection import johnsonlindenstraussmindim
johnsonlindenstraussmindimnsamples1e6 eps05
```

```

Example

- See The JohnsonLindenstrauss bound for embedding with random projections for a theoretical explication on the JohnsonLindenstrauss lemma and an empirical validation using sparse random matrices

References

- Sanjoy Dasgupta and Anupam Gupta 1999 An elementary proof of the JohnsonLindenstrauss Lemma Gaussian random projection

The sklearnrandomprojectionGaussianRandomProjection reduces the dimensionality by projecting the original input space on a randomly generated matrix where components are drawn from the following distribution ¶01

¶¶¶¶¶¶¶¶¶¶

Here a small excerpt which illustrates how to use the Gaussian random projection transformer

scikitlearn user guide Release 0213

```
import numpy as np
from sklearn import randomprojection
X = np.random.rand(100, 10000)
transformer = randomprojection.GaussianRandomProjection
X_new = transformer.fit_transform(X)
X_new.shape
(100, 3947)
```

Sparse random projection

The `sklearn.randomprojection.SparseRandomProjection` reduces the dimensionality by projecting the original input space using a sparse random matrix. Sparse random matrices are an alternative to dense Gaussian random projection matrix that guarantees similar embedding quality while being much more memory efficient and allowing faster computation of the projected data. If we define $s = 1/\text{density}$ the elements of the random matrix are drawn from

$$\begin{cases} \sqrt{\frac{2}{s}} & \text{with probability } \frac{1}{2} \\ -\sqrt{\frac{2}{s}} & \text{with probability } \frac{1}{2} \\ 0 & \text{with probability } 1 - \frac{1}{s} \end{cases}$$

where $\frac{1}{s}$ components is the size of the projected subspace. By default the density of non zero elements is set to the minimum density as recommended by Ping Li et al $1/\sqrt{\text{features}}$. Here a small excerpt which illustrates how to use the sparse random projection transformer

```
import numpy as np
from sklearn import randomprojection
X = np.random.rand(100, 10000)
transformer = randomprojection.SparseRandomProjection
X_new = transformer.fit_transform(X)
X_new.shape
(100, 3947)
```

357 Kernel Approximation
This submodule contains functions that approximate the feature mappings that correspond to certain kernels as they are used for example in support vector machines see Support Vector Machines. The following feature functions perform nonlinear transformations of the input which can serve as a basis for linear classification or other algorithms. The advantage of using approximate explicit feature maps compared to the kernel trick which makes use of feature maps implicitly is that explicit mappings can be better suited for online learning and can significantly reduce the cost of learning with very large datasets. Standard kernelized SVMs do not scale well to large datasets but using an

scikitlearn user guide Release 0213

approximate kernel map it is possible to use much more efficient linear SVMs In particular the combination of kernel map approximations with SGDClassifier can make nonlinear learning on large datasets possible
Since there has not been much empirical work using approximate embeddings it is advisable to compare results against exact kernel methods when possible
See also

Polynomial regression extending linear models with basis functions for an exact polynomial transformation
Nystroem Method for Kernel Approximation

The Nystroem method as implemented in Nystroem is a general method for lowrank approximations of kernels
It achieves this by essentially subsampling the data on which the kernel is evaluated By default Nystroem uses the rbf kernel but it can use any kernel function or a precomputed kernel matrix The number of samples used which is also the dimensionality of the features computed is given by the parameter ncomponents
Radial Basis Function Kernel

TheRBFSampler constructs an approximate mapping for the radial basis function kernel also known as Random Kitchen Sinks RR2007 This transformation can be used to explicitly model a kernel map prior to applying a linear algorithm for example a linear SVM (Support Vector Machine)

```
from sklearn.kernelapproximation import RBFSampler
from sklearn.linear_model import SGDClassifier
X = [[0,0,1,1,1,0,0,1],
     [0,0,1,1]]
rbf = RBFSampler(gamma=1, random_state=1)
X_features = rbf.fit_transform(X)
clf = SGDClassifier(max_iter=5,
                    alpha=0.0001, average=False, class_weight=None,
                    early_stopping=False, epsilon=0.1, eta=0.001, fit_intercept=True,
                    l1_ratio=0.15, learning_rate='optimal', loss='hinge', max_iter=5,
                    n_iter_no_change=5, n_jobs=None, penalty='l2', power_t=0.5,
                    random_state=None, shuffle=True, tol=0.0001, validation_fraction=0.1,
                    verbose=0, warm_start=False)
clf.fit(X_features, y)
print(clf.score(X_features, y))
```

The mapping relies on a Monte Carlo approximation to the kernel values The fit function performs the Monte Carlo sampling whereas the transform method performs the mapping of the data Because of the inherent randomness of the process results may vary between different calls to the fit function
The fit function takes two arguments ncomponents which is the target dimensionality of the feature transform and gamma the parameter of the RBF kernel A higher ncomponents will result in a better approximation of the kernel and will yield results more similar to those produced by a kernel SVM (Support Vector Machine) Note that “fitting” the feature function does not actually depend on the data given to the fit function Only the dimensionality of the data is used Details on the method can be found in RR2007
For a given value of ncomponents RBFSampler is often less accurate as Nystroem RBFSampler is cheaper to compute though making use of larger feature spaces more efficient
Examples

•Explicit feature map approximation for RBF (Radial Basis Function) kernels

Additive Chi Squared Kernel

The additive chi squared kernel is a kernel on histograms often used in computer vision

The additive chi squared kernel as used here is given by

$$K(x,y) = \sum_{i=1}^n \frac{1}{2} \left(\frac{x_i}{y_i} + \frac{y_i}{x_i} \right)$$

This is not exactly the same as sklearnmetricsadditivechi2kernel The authors of VZ2010 prefer the version above as it is always positive definite Since the kernel is additive it is possible to treat all components separately for embedding This makes it possible to sample the Fourier transform in regular intervals instead of approximating using Monte Carlo sampling

The classAdditiveChi2Sampler implements this component wise deterministic sampling Each component is sampled $\frac{1}{2}$ times yielding 2×1 dimensions per input dimension the multiple of two stems from the real and complex part of the Fourier transform In the literature $\frac{1}{2}$ is usually chosen to be 1 or 2 transforming the dataset to $2 \times n$ features in the case of $\frac{1}{2} = 2$

The approximate feature map provided by AdditiveChi2Sampler can be combined with the approximate feature map provided by RBFSampler to yield an approximate feature map for the exponentiated chi squared kernel See theVZ2010 for details and VVZ2010 for combination with the RBFSampler

Skewed Chi Squared Kernel

The skewed chi squared kernel is given by

$$K(x,y) = \prod_{i=1}^n \left(\frac{x_i}{y_i} \right)^{\frac{1}{2}} \left(\frac{y_i}{x_i} \right)^{\frac{1}{2}}$$

It has properties that are similar to the exponentiated chi squared kernel often used in computer vision but allows for a simple Monte Carlo approximation of the feature map

scikitlearn user guide Release 0213

The usage of the SkewedChi2Sampler is the same as the usage described above for the RBFSampler. The only difference is in the free parameter that is called γ . For a motivation for this mapping and the mathematical details see LS2010

Mathematical Details

Kernel methods like support vector machines or kernelized PCA (Principal Component Analysis) rely on a property of reproducing kernel Hilbert spaces. For any positive definite kernel function κ a so called Mercer kernel it is guaranteed that there exists a mapping ϕ into a Hilbert space \mathcal{H} such that

$$\kappa(x, y) = \langle \phi(x), \phi(y) \rangle$$

Where $\langle \cdot, \cdot \rangle$ denotes the inner product in the Hilbert space

If an algorithm such as a linear support vector machine or PCA (Principal Component Analysis) relies only on the scalar product of data points x, y one may use the value of $\kappa(x, y)$ which corresponds to applying the algorithm to the mapped data points $\phi(x), \phi(y)$. The advantage of using κ is that the mapping ϕ never has to be calculated explicitly allowing for arbitrary large features even infinite

One drawback of kernel methods is that it might be necessary to store many kernel values $\kappa(x_i, x_j)$ during optimization. If a kernelized classifier is applied to new data x_{new} $\kappa(x_{\text{new}}, x_i)$ needs to be computed to make predictions possibly for many different x_i in the training set.

The classes in this submodule allow to approximate the embedding ϕ thereby working explicitly with the representations $\phi(x)$ which obviates the need to apply the kernel or store training examples.

References

358 Pairwise metrics Affinities and Kernels

The sklearn.metrics.pairwise submodule implements utilities to evaluate pairwise distances or affinity of sets of samples.

This module contains both distance metrics and kernels. A brief summary is given on the two here.

Distance metrics are functions $d(a, b)$ such that $d(a, b) \geq d(a, c)$ if objects a and b are considered “more similar” than objects a and c . Two objects exactly alike would have a distance of zero. One of the most popular examples is Euclidean distance. To be a ‘true’ metric it must obey the following four conditions:

- 1. $d(a, b) \geq 0$ for all a and b .
- 2. $d(a, b) = 0$ if and only if $a = b$ positive definiteness.
- 3. $d(a, b) = d(b, a)$ symmetry.
- 4. $d(a, c) \leq d(a, b) + d(b, c)$ the triangle inequality.

Kernels are measures of similarity i.e. $s(a, b) \geq s(a, c)$ if objects a and b are considered “more similar” than objects a and c . A kernel must also be positive semidefinite.

There are a number of ways to convert between a distance metric and a similarity measure such as a kernel. Let D be the distance and S be the kernel:

$$S = \frac{1}{n \cdot \exp(D)} \quad \text{where one heuristic for choosing } \gamma \text{ is } \gamma = \frac{1}{\sqrt{2 \cdot \text{num_features}}}$$

35 Dataset transformations 621

scikitlearn user guide Release 0213

The distances between the row vectors of X and the row vectors of Y can be evaluated using `pairwise_distances`. If Y is omitted the pairwise distances of the row vectors of X are calculated. Similarly `pairwise_kernels` can be used to calculate the kernel between X and Y using different kernel functions. See the API (Application Programming Interface) reference for more details.

```
import numpy as np
from sklearn.metrics import pairwise_distances
from sklearn.metrics.pairwise import pairwise_kernels
X = np.array([2, 3, 3, 5, 5, 8])
Y = np.array([1, 0, 2, 1])
pairwise_distances(X, Y, metric='manhattan')
array([[4, 2],
       [7, 5],
       [12, 10],
       [3, 0],
       [5, 8],
       [5, 0]])
pairwise_kernels(X, Y, metric='linear')
array([[2, 7],
       [3, 11],
       [5, 18]])
```

Cosine similarity

`cosine_similarity` computes the L2-normalized dot product of vectors. That is, if x and y are row vectors, their cosine similarity is defined as

$$\frac{x \cdot y}{\|x\| \|y\|}$$

This is called cosine similarity because Euclidean L2 normalization projects the vectors onto the unit sphere and their dot product is then the cosine of the angle between the points denoted by the vectors.

This kernel is a popular choice for computing the similarity of documents represented as tfidf vectors.

`cosine_similarity` accepts sparse matrices. Note that the tfidf functionality in `sklearn.feature_extraction.text` can produce normalized vectors in which case `cosine_similarity` is equivalent to `linear_kernel` (only slower).

References

- CD Manning, P. Raghavan and H. Schütze. 2008. Introduction to Information Retrieval. Cambridge University Press. <https://nlp.stanford.edu/IR-book/html/htmledition/the-vector-space-model-for-scoring-1.html>

Linear kernel

The function `linear_kernel` computes the linear kernel, which is a special case of `polynomial_kernel` with `degree=1` and `coef0=0` (homogeneous). If x and y are column vectors, their linear kernel is

$$x \cdot y^T$$

Polynomial kernel

The function `polynomialkernel` computes the degreed polynomial kernel between two vectors The polynomial kernel represents the similarity between two vectors Conceptually the polynomial kernels considers not only the similarity between vectors under the same dimension but also across dimensions When used in machine learning algorithms this allows to account for feature interaction

The polynomial kernel is defined as

$$k(x,y) = (x^T y + c)^d$$

where

- x, y are the input vectors
 - d is the kernel degree
- If $d = 0$ the kernel is said to be homogeneous

Sigmoid kernel

The function `sigmoidkernel` computes the sigmoid kernel between two vectors The sigmoid kernel is also known as hyperbolic tangent or Multilayer Perceptron because in the neural network field it is often used as neuron activation function It is defined as

$$k(x,y) = \tanh(\gamma x^T y + c)$$

where

- x, y are the input vectors
- γ is known as slope
- c is known as intercept

RBF (Radial Basis Function) kernel

The function `rbfkernel` computes the radial basis function RBF (Radial Basis Function) kernel between two vectors This kernel is defined as

$$k(x,y) = \exp(-\gamma \|x - y\|^2)$$

where x and y are the input vectors If $\gamma = 2$ the kernel is known as the Gaussian kernel of variance $\frac{1}{2}$

Laplacian kernel

The function `laplaciankernel` is a variant on the radial basis function kernel defined as

$$k(x,y) = \exp(-\gamma (\|x - y\|_1 + 1))$$

where x and y are the input vectors and $\|x - y\|_1$ is the Manhattan distance between the input vectors

It has proven useful in ML applied to noiseless data See eg Machine learning for quantum mechanics in a nutshell

scikitlearn user guide Release 0213

Chisquared kernel

The chisquared kernel is a very popular choice for training nonlinear SVMs in computer vision applications It can be computed using chi2kernel and then passed to an sklearnsvmSVC withkernelprecomputed

```

```

```
svm SVCkernelprecomputedfitK y
```

```
svmpredictK
```

```
array0 1 0 1
```

It can also be directly used as the kernel argument

```
svm SVCkernelchi2kernelfitX y
```

```
svmpredictX
```

```
array0 1 0 1
```

The chi squared kernel is given by

$\frac{1}{2} \sum \exp$

$-\frac{1}{2} \sum$

$\frac{1}{2} \sum - \frac{1}{2} \sum$

$\frac{1}{2} \sum$

The data is assumed to be nonnegative and is often normalized to have an L1norm of one The normalization is rationalized with the connection to the chi squared distance which is a distance between discrete probability distributions

The chi squared kernel is most commonly used on histograms bags of visual words

36 Dataset loading utilities

The sklearn datasets package embeds some small toy datasets as introduced in the Getting Started section

This package also features helpers to fetch larger datasets commonly used by the machine learning community to

benchmark algorithms on data that comes from the ‘real world’

36 Dataset loading utilities 625

scikitlearn user guide Release 0213

To evaluate the impact of the scale of the dataset `nsamples` and `nfeatures` while controlling the statistical properties of the data typically the correlation and informativeness of the features it is also possible to generate synthetic data

361 General dataset API (Application Programming Interface)

There are three main kinds of dataset interfaces that can be used to get datasets depending on the desired type of dataset

The dataset loaders They can be used to load small standard datasets described in the Toy datasets section

The dataset fetchers They can be used to download and load larger datasets described in the Real world datasets section

Both loaders and fetchers functions return a dictionarylike object holding at least two items an array of shape `nsamples nfeatures` with key `data` except for `20newsgroups` and a numpy array of length `nsamples` containing the target values with key `target`

It's also possible for almost all of these function to constrain the output to be a tuple containing only the data and the target by setting the `returnXy` parameter to `True`

The datasets also contain a full description in their `DESCR` attribute and some contain `featurenames` and `targetnames` See the dataset descriptions below for details

The dataset generation functions They can be used to generate controlled synthetic datasets described in the Generated datasets section

These functions return a tuple `X y` consisting of a `nsamples nfeatures` numpy array `X` and an array of length `nsamples` containing the targets `y`

In addition there are also miscellaneous tools to load datasets of other formats or from other locations described in the Loading other datasets section

362 Toy datasets

scikitlearn comes with a few small standard datasets that do not require to download any file from some external website

They can be loaded using the following functions

`loadboston` `returnXy` Load and return the boston houseprices dataset regression

`loadiris` `returnXy` Load and return the iris dataset classification

`loaddiabetes` `returnXy` Load and return the diabetes dataset regression

`loaddigits` `nclass` `returnXy` Load and return the digits dataset classification

`loadlinnerud` `returnXy` Load and return the linnerud dataset multivariate regression

`loadwine` `returnXy` Load and return the wine dataset classification

`loadbreastcancer` `returnXy` Load and return the breast cancer wisconsin dataset classification

These datasets are useful to quickly illustrate the behavior of the various algorithms implemented in scikitlearn They are however often too small to be representative of real world machine learning tasks

Date July 1988

The famous Iris database first used by Sir RA Fisher The dataset is taken from Fisher's paper Note that it's the

same as in R but not as in the UCI Machine Learning Repository which has two wrong data points

This is perhaps the best known database to be found in the pattern recognition literature Fisher's paper is a classic in

the field and is referenced frequently to this day See Duda Hart for example The data set contains 3 classes of

50 instances each where each class refers to a type of iris plant One class is linearly separable from the other 2 the

latter are NOT linearly separable from each other

Recognition of Handwritten Digits

The data set contains images of handwritten digits 10 classes where each class refers to a digit

Preprocessing programs made available by NIST were used to extract normalized bitmaps of handwritten digits from a preprinted form From a total of 43 people 30 contributed to the training set and different 13 to the test set 32x32 bitmaps are divided into nonoverlapping blocks of 4x4 and the number of on pixels are counted in each block This generates an input matrix of 8x8 where each element is an integer in the range 016 This reduces dimensionality and gives invariance to small distortions

363 Real world datasets

scikitlearn provides tools to load larger datasets downloading them if necessary

They can be loaded using the following functions

fetcholivettifaces datahome shuffle Load the Olivetti faces dataset from ATT classification

fetch20newsgroups datahome subset Load the filenames and data from the 20 newsgroups

dataset classification

fetch20newsgroupsvectorized subset Load the 20 newsgroups dataset and vectorize it into token

counts classification

fetchlfwpeople datahome funneled Load the Labeled Faces in the Wild LFW people dataset

classification

fetchlfwpairs subset datahome Load the Labeled Faces in the Wild LFW pairs dataset

classification

fetchcovtype datahome Load the covertype dataset classification

fetchrcv1 datahome subset Load the RCV1 multilabel dataset classification

fetchkddcup99 subset datahome shuffle Load the kddcup99 dataset classification

fetchcaliforniahousing datahome Load the California housing dataset regression

The Olivetti faces dataset

This dataset contains a set of face images taken between April 1992 and April 1994 at ATT Laboratories Cam bridge The sklearndatasetsfetcholivettifaces function is the data fetching caching function that downloads the data archive from ATT

As described on the original website

There are ten different images of each of 40 distinct subjects For some subjects the images were taken

634 Chapter 3 User Guide

scikitlearn user guide Release 0213

at different times varying the lighting facial expressions open closed eyes smiling not smiling and facial details glasses no glasses All the images were taken against a dark homogeneous background with the subjects in an upright frontal position with tolerance for some side movement

Data Set Characteristics

Classes 40

Samples total 400

Dimensionality 4096

Features real between 0 and 1

The image is quantized to 256 grey levels and stored as unsigned 8bit integers the loader will convert these to floating point values on the interval 0 1 which are easier to work with for many algorithms

The “target” for this database is an integer from 0 to 39 indicating the identity of the person pictured however with only 10 examples per class this relatively small dataset is more interesting from an unsupervised or semisupervised perspective

The original dataset consisted of 92 x 112 while the version available here consists of 64x64 images

When using these images please give credit to ATT Laboratories Cambridge

The 20 newsgroups text dataset

The 20 newsgroups dataset comprises around 18000 newsgroups posts on 20 topics split in two subsets one for training or development and the other one for testing or for performance evaluation The split between the train and test set is based upon a messages posted before and after a specific date

This module contains two loaders The first one sklearndatasetsfetch20newsgroups returns a list of the raw texts that can be fed to text feature extractors such as sklearnfeatureextractiontext CountVectorizer with custom parameters so as to extract feature vectors The second one sklearn datasetsfetch20newsgroupsvectorized returns readytouse features ie it is not necessary to use a feature extractor

Data Set Characteristics

Classes 20

Samples total 18846

Converting text to vectors
In order to feed predictive or clustering models with the text data one first need to turn the text into vectors
of numerical values suitable for statistical analysis This can be achieved with the utilities of the sklearn
featureextractiontext as demonstrated in the following example that extract TFIDF vectors of unigram
tokens from a subset of 20news
from sklearnfeatureextractiontext import TfidfVectorizer
categories altatheism talkreligionmisc
compgraphics scispace

sklearn.datasets.fetch_20newsgroups_vectorized is a function which returns ready to use token

counts features instead of file names

Filtering text for more realistic training

It is easy for a classifier to overfit on particular things that appear in the 20 Newsgroups data such as newsgroup

headers Many classifiers achieve very high Fscores but their results would not generalize to other documents that

aren't from this window of time

For example let's look at the results of a multinomial Naive Bayes classifier which is fast to train and achieves a

decent Fscore

```
from sklearn.naive_bayes import MultinomialNB
```

```
from sklearn import metrics
```

```
newsgroup_test, fetch_20newsgroup_subset_test
```

```
categories, categories
```

```
vector_test, vectorizer, transform_newsgroup_test_data
```

```
clf = MultinomialNB(alpha=0.1)
```

```
clf.fit(vector_test, newsgroup_strain_target)
```

```
MultinomialNB(alpha=0.01, class_prior=None, fit_prior=True)
```

```
pred = clf.predict(vector_test)
```

```
metrics.f1_score(newsgroup_test_target, pred, average='macro')
```

0.88213

The example Classification of text documents using sparse features shuffles the training and test data instead of

segmenting by time and in that case multinomial Naive Bayes gets a much higher Fscore of 0.88 Are you suspicious

yet of what's going on inside this classifier

Let's take a look at what the most informative features are

```
import numpy as np
```

```
def show_top10_classifier(vectorizer, categories)
```

```
feature_names = np.asarray(vectorizer.get_feature_names())
```

```
for i, category in enumerate(categories)
```

```
top10 = np.argsort(classifier.coef_[0])
```

```
print('ss', category, join(feature_names[top10])
```

```
show_top10_clf(vectorizer, newsgroup_strain_target_names)
```

```
altatheism.edu it and in you that is of to the
```

```
compgraphics.edu in graphics it is for and of to the
```

```
scispace.edu it that is in and space to of the
```

```
talkreligionmisc not it you in is that and to of the
```

You can now see many things that these features have overfit to

36 Dataset loading utilities 637

scikitlearn user guide Release 0213

- Almost every group is distinguished by whether headers such as NNTPPostingHost and Distribution appear more or less often
- Another significant feature involves whether the sender is affiliated with a university as indicated either by their headers or their signature
- The word "article" is a significant feature based on how often people quote previous posts like this "In article article ID name email address wrote"
- Other features match the names and email addresses of particular people who were posting at the time

With such an abundance of clues that distinguish newsgroups the classifiers barely have to identify topics from text at all and they all perform at the same high level

For this reason the functions that load 20 Newsgroups data provide a parameter called remove telling it what kinds of information to strip out of each file remove should be a tuple containing any subset of headers footers quotes telling it to remove headers signature blocks and quotation blocks respectively

```
newsgroupstest fetch20newsgroupssubsettest
removeheaders footers quotes
categoriescategories
vectorstest vectorizertransformnewsgroupstestdata
pred clfpredictvectorstest
metricsf1scorepred newsgroupstesttarget averagemacro
077310
```

This classifier lost over a lot of its Fscore just because we removed metadata that has little to do with topic classification It loses even more if we also strip this metadata from the training data

```
newsgroupstrain fetch20newsgroupssubsettrain
removeheaders footers quotes
categoriescategories
vectors vectorizerfittransformnewsgroupstraindata
clf MultinomialNBalpha01
clffitvectors newsgroupstraintarget
MultinomialNBalpha001 classpriorNone fitpriorTrue
vectorstest vectorizertransformnewsgroupstestdata
pred clfpredictvectorstest
metricsf1scorenewsgroupstesttarget pred averagemacro
076995
```

Some other classifiers cope better with this harder version of the task Try running Sample pipeline for text feature extraction and evaluation with and without the filter option to compare the results

Recommendation

When evaluating text classifiers on the 20 Newsgroups data you should strip newsgrouprelated metadata In scikitlearn you can do this by setting removeheaders footers quotes The Fscore will be lower because it is more realistic

Examples

- Sample pipeline for text feature extraction and evaluation
- Classification of text documents using sparse features

scikitlearn user guide Release 0213

The Labeled Faces in the Wild face recognition dataset

This dataset is a collection of JPEG pictures of famous people collected over the internet all details are available on the official website

httpviswwwwcsumassedulfw

Each picture is centered on a single face The typical task is called Face Verification given a pair of two pictures a binary classifier must predict whether the two images are from the same person

An alternative task Face Recognition or Face Identification is given the picture of the face of an unknown person identify the name of the person by referring to a gallery of previously seen pictures of identified persons

Both Face Verification and Face Recognition are tasks that are typically performed on the output of a model trained to perform Face Detection The most popular model for Face Detection is called ViolaJones and is implemented in the OpenCV library The LFW faces were extracted by this face detector from various online websites

Data Set Characteristics

Classes 5749

Samples total 13233

Dimensionality 5828

Features real between 0 and 255

Usage

scikitlearn provides two loaders that will automatically download cache parse the metadata files decode the jpeg and convert the interesting slices into memmapped numpy arrays This dataset size is more than 200 MB The first load typically takes more than a couple of minutes to fully decode the relevant part of the JPEG files into numpy arrays If the dataset has been loaded once the following times the loading times less than 200ms by using a memmapped version memoized on the disk in the scikitlearndatalfwhome folder using joblib

The first loader is used for the Face Identification task a multiclass classification task hence supervised learning

```
from sklearndatasets import fetchlfwpeople
lfwpeople fetchlfwpeopleminfacesperperson70 resize04

Kddcup 99 dataset

The KDD Cup '99 dataset was created by processing the tcpdump portions of the 1998 DARPA Intrusion Detection System IDS Evaluation dataset created by MIT Lincoln Lab 1 The artificial data described on the dataset's

homepage was generated using a closed network and handinjected attacks to produce a large number of different

types of attack with normal activity in the background As the initial goal was to produce a large training set for

supervised learning algorithms there is a large proportion 801 of abnormal data which is unrealistic in real world

and inappropriate for unsupervised anomaly detection which aims at detecting 'abnormal' data ie

1 qualitatively different from normal data

2 in large minority among the observations

We thus transform the KDD Data set into two different data sets SA and SF

SA is obtained by simply selecting all the normal data and a small proportion of abnormal data to gives an anomaly proportion of 1

SF is obtained as in 2 by simply picking up the data whose attribute loggedin is positive thus focusing on the

intrusion attack which gives a proportion of 03 of attack

http and smtp are two subsets of SF corresponding with third feature equal to 'http' resp to 'smtp'

General KDD structure

Samples total 4898431

Dimensionality 41

Features discrete int or continuous float

Targets str 'normal' or name of the anomaly type

SA structure

Samples total 976158

Dimensionality 41

Features discrete int or continuous float

Targets str 'normal' or name of the anomaly type

SF structure

Samples total 699691

Dimensionality 4

Features discrete int or continuous float

Targets str 'normal' or name of the anomaly type

scikitlearn user guide Release 0213

http structure

Samples total 619052

Dimensionality 3

Features discrete int or continuous float

Targets str 'normal' or name of the anomaly type

smtp structure

Samples total 95373

Dimensionality 3

Features discrete int or continuous float

Targets str 'normal' or name of the anomaly type

sklearn.datasets.fetch_kddcup99 will load the kddcup99 dataset it returns a dictionarylike object with the feature matrix in the data member and the target values in target The dataset will be downloaded from the web if necessary

California Housing dataset

Data Set Characteristics

Number of Instances 20640

Number of Attributes 8 numeric predictive attributes and the target

Attribute Information

- MedInc median income in block
- HouseAge median house age in block
- AveRooms average number of rooms
- AveBedrms average number of bedrooms
- Population block population
- AveOccup average house occupancy
- Latitude house block latitude
- Longitude house block longitude

Missing Attribute Values None

This dataset was obtained from the StatLib repository <http://lib.stat.cmu.edu/datasets>

The target variable is the median house value for California districts

This dataset was derived from the 1990 US census using one row per census block group A block group is the smallest geographical unit for which the US Census Bureau publishes sample data a block group typically has a population of 600 to 3000 people

It can be downloaded using the `sklearn.datasets.fetch_california_housing` function

364 Generated datasets

In addition scikitlearn includes various random sample generators that can be used to build artificial datasets of controlled size and complexity

Generators for classification and clustering

These generators produce a matrix of features and corresponding discrete targets

Single label

Bothmakeblobs andmakeclassification create multiclass datasets by allocating each class one or more normallydistributed clusters of points makeblobs provides greater control regarding the centers and standard deviations of each cluster and is used to demonstrate clustering makeclassification specialises in introducing noise by way of correlated redundant and uninformative features multiple Gaussian clusters per class and linear transformations of the feature space

makegaussianquantiles divides a single Gaussian cluster into nearequalsize classes separated

by concentric hyperspheres makehastie102 generates a similar binary 10dimensional problem

makecircles andmakemoons gener

ate 2d binary classification datasets that are challenging to certain algorithms eg centroidbased clustering or linear classification including optional Gaussian noise They are useful for visualisation makecircles produces Gaussian data with a spherical decision boundary for binary classification while makemoons produces two interleaving half circles

644 Chapter 3 User Guide

scikitlearn user guide Release 0213

Multilabel

makemultilabelclassification generates random samples with multiple labels reflecting a bag of words drawn from a mixture of topics The number of topics for each document is drawn from a Poisson distribution and the topics themselves are drawn from a fixed random distribution Similarly the number of words is drawn from Poisson with words drawn from a multinomial where each topic defines a probability distribution over words Simplifications with respect to true bagofwords mixtures include

- Pertopic word distributions are independently drawn where in reality all would be affected by a sparse base distribution and would be correlated
- For a document generated from multiple topics all topics are weighted equally in generating its bag of words
- Documents without labels words at random rather than from a base distribution

Biclustering

makebicclusters shape nclusters noise Generate an array with constant block diagonal structure for biclustering

makecheckerboard shape nclusters Generate an array with block checkerboard structure for bi clustering

Generators for regression

makeregression produces regression targets as an optionallysparse random linear combination of random fea tures with noise Its informative features may be uncorrelated or low rank few features account for most of the variance

Other regression generators generate functions deterministically from randomized features

makesparseuncorrelated produces a target as a linear combination of four features with fixed coef ficients Others encode explicitly nonlinear relations makefriedman1 is related by polynomial and sine transforms makefriedman2 includes feature multiplication and reciprocation and makefriedman3 is similar with an arctan transformation on the target

Generators for manifold learning

makescurve nsamples noise randomstate Generate an S curve dataset

makeswissroll nsamples noise randomstate Generate a swiss roll dataset

36 Dataset loading utilities 645

scikitlearn user guide Release 0.21.3

Generators for decomposition

`make_lowrank_matrix(nsamples, ...)` Generate a mostly low rank matrix with bell-shaped singular values

`make_sparse_coded_signal(nsamples, ...)` Generate a signal as a sparse combination of dictionary elements

`make_sparse_pdmatrix(ndim, random_state=...)` Generate a random symmetric positive definite matrix

`make_sparse_pdmatrix(dim, alpha=...)` Generate a sparse symmetric definite positive matrix

365 Loading other datasets

Sample images

Scikit-learn also embeds a couple of sample JPEG images published under Creative Commons license by their authors

Those images can be useful to test algorithms and pipeline on 2D data

`load_sample_images()` Load sample images for image manipulation

`load_sample_image(image_name)` Load the numpy array of a single sample image

Warning: The default coding of images is based on the `uint8` dtype to spare memory. Often machine learning

algorithms work best if the input is converted to a floating point representation first. Also if you plan to use

`matplotlib.pyplot.imshow()` don't forget to scale to the range `[0, 1]` as done in the following example

Examples

• Color Quantization using KMeans

Datasets in `svmlight` / `libsvm` format

scikit-learn includes utility functions for loading datasets in the `svmlight` / `libsvm` format. In this format each line

takes the form `label feature_id feature_value feature_id feature_value`

This format is especially suitable for sparse datasets. In this module `scipy.sparse` CSR (Compressed Sparse Row) matrices are used for `X` and

numpy arrays are used for `y`

You may load a dataset like as follows

```
from sklearn.datasets import load_svmlight_file
```

```
X_train, y_train = load_svmlight_file(path_to_train_dataset.txt)
```

```
scikitlearn user guide Release 0213
You may also load two or more datasets at once
Xtrain ytrain Xtest ytest loadsvmlightfiles
pathtotraindataset.txt pathtotestdataset.txt
```

In this case Xtrain and Xtest are guaranteed to have the same number of features Another way to achieve the same result is to fix the number of features

```
Xtest ytest loadsvmlightfile
pathtotestdataset.txt nfeaturesXtrain.shape[1]
```

```

Loading from external datasets

scikitlearn works on any numeric data stored as numpy arrays or scipy sparse matrices Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable

Here are some recommended ways to load standard columnar data into a format usable by scikitlearn

• pandasio provides tools to read data from common formats including CSV Excel JSON and SQL DataFrames may also be constructed from lists of tuples or dicts Pandas handles heterogeneous data smoothly and provides tools for manipulation and conversion into a numeric array suitable for scikitlearn

• scipyio specializes in binary formats often used in scientific computing context such as mat and arff

• numpyroutinesio for standard loading of columnar data into numpy arrays

• scikitlearn’s datasetsloadsvmlightfile for the svmlight or libSVM sparse format

• scikitlearn’s datasetsloadfiles for directories of text files where the name of each directory is the name of each category and each file inside of each directory corresponds to one sample from that category For some miscellaneous data such as images videos and audio you may wish to refer to

• skimageio or Imageio for loading images and videos into numpy arrays

• scipyiowavfileread for reading WAV files into a numpy array

Categorical or nominal features stored as strings common in pandas DataFrames will need converting to numerical features using sklearnpreprocessingOneHotEncoder or sklearnpreprocessing

OrdinalEncoder or similar See Preprocessing data

36 Dataset loading utilities 649

scikitlearn user guide Release 0213

Note if you manage your own numerical data it is recommended to use an optimized file format such as HDF5 to reduce data load times Various libraries such as H5Py PyTables and pandas provides a Python interface for reading and writing data in that format

37 Computing with scikitlearn

371 Strategies to scale computationally bigger data

For some applications the amount of examples features or both and/or the speed at which they need to be processed are challenging for traditional approaches In these cases scikitlearn has a number of options you can consider to make your system scale

Scaling with instances using outofcore learning

Outofcore or “external memory” learning is a technique used to learn from data that cannot fit in a computer’s main memory RAM

Here is a sketch of a system designed to achieve this goal

1 a way to stream instances

2 a way to extract features from instances

3 an incremental algorithm

Streaming instances

Basically 1 may be a reader that yields instances from files on a hard drive a database from a network stream etc

However details on how to achieve this are beyond the scope of this documentation

Extracting features

2 could be any relevant way to extract features among the different feature extraction methods supported by scikit learn However when working with data that needs vectorization and where the set of features or values is not known in advance one should take explicit care A good example is text classification where unknown terms are likely to be found during training It is possible to use a stateful vectorizer if making multiple passes over the data is reasonable from an application point of view Otherwise one can turn up the difficulty by using a stateless feature extractor Currently the preferred way to do this is to use the so-called hashing trick as implemented by sklearn featureextractionFeatureHasher for datasets with categorical variables represented as list of Python dicts or sklearnfeatureextractiontextHashingVectorizer for text documents

Incremental learning

Finally for 3 we have a number of options inside scikitlearn Although not all algorithms can learn incrementally ie without seeing all the instances at once all estimators implementing the partialfit API (Application Programming Interface) are candidates Actually the ability to learn incrementally from a minibatch of instances sometimes called “online learning” is key to outofcore learning as it guarantees that at any given time there will be only a small amount of instances in the

650 Chapter 3 User Guide

scikitlearn user guide Release 0213

main memory Choosing a good size for the minibatch that balances relevancy and memory footprint could involve some tuning1

Here is a list of incremental estimators for different tasks

- Classification
 - sklearnnaivebayesMultinomialNB
 - sklearnnaivebayesBernoulliNB
 - sklearnlinearmodelPerceptron
 - sklearnlinearmodelSGDClassifier
 - sklearnlinearmodelPassiveAggressiveClassifier
 - sklearnneuralnetworkMLPClassifier
- Regression
 - sklearnlinearmodelSGDRegressor
 - sklearnlinearmodelPassiveAggressiveRegressor
 - sklearnneuralnetworkMLPRegressor
- Clustering
 - sklearnclusterMiniBatchKMeans
 - sklearnclusterBirch
- Decomposition feature Extraction
 - sklearndecompositionMiniBatchDictionaryLearning
 - sklearndecompositionIncrementalPCA
 - sklearndecompositionLatentDirichletAllocation
- Preprocessing
 - sklearnpreprocessingStandardScaler
 - sklearnpreprocessingMinMaxScaler
 - sklearnpreprocessingMaxAbsScaler

For classification a somewhat important thing to note is that although a stateless feature extraction routine may be able to cope with newunseen attributes the incremental learner itself may be unable to cope with newunseen targets classes In this case you have to pass all the possible classes to the first partialfit call using the classes parameter

Another aspect to consider when choosing a proper algorithm is that not all of them put the same importance on each example over time Namely the Perceptron is still sensitive to badly labeled examples even after many examples whereas the SGDandPassiveAggressive families are more robust to this kind of artifacts Conversely the latter also tend to give less importance to remarkably different yet properly labeled examples when they come late in the stream as their learning rate decreases over time

1Depending on the algorithm the minibatch size can influence results or not SGD PassiveAggressive and discrete NaiveBayes are truly online and are not affected by batch size Conversely MiniBatchKMeans convergence rate is affected by the batch size Also its memory footprint can vary dramatically with batch size

37 Computing with scikitlearn 651

scikitlearn user guide Release 0213

Examples

Finally we have a fullfledged example of Outofcore classification of text documents. It is aimed at providing a starting point for people wanting to build outofcore learning systems and demonstrates most of the notions discussed above.

Furthermore it also shows the evolution of the performance of different algorithms with the number of processed examples.

Now looking at the computation time of the different parts we see that the vectorization is much more expensive than learning itself. From the different algorithms MultinomialNB is the most expensive but its overhead can be mitigated by increasing the size of the minibatches. Exercise: change minibatchsize to 100 and 10000 in the program and compare.

Notes

372 Computational Performance

For some applications the performance mainly latency and throughput at prediction time of estimators is crucial It may also be of interest to consider the training throughput but this is often less important in a production setup where it often takes place offline

We will review here the orders of magnitude you can expect from a number of scikitlearn estimators in different contexts and provide some tips and tricks for overcoming performance bottlenecks

Prediction latency is measured as the elapsed time necessary to make a prediction eg in microseconds Latency is often viewed as a distribution and operations engineers often focus on the latency at a given percentile of this distribution eg the 90 percentile

Prediction throughput is defined as the number of predictions the software can deliver in a given amount of time eg in predictions per second

An important aspect of performance optimization is also that it can hurt prediction accuracy Indeed simpler models eg linear instead of nonlinear or with fewer parameters often run faster but are not always able to take into account the same exact properties of the data as more complex ones

Prediction Latency

One of the most straightforward concerns one may have when usingchoosing a machine learning toolkit is the latency at which predictions can be made in a production environment

The main factors that influence the prediction latency are

- 1 Number of features

scikitlearn user guide Release 0213

2 Input data representation and sparsity

3 Model complexity

4 Feature extraction

A last major parameter is also the possibility to do predictions in bulk or oneatotime mode

Bulk versus Atomic mode

In general doing predictions in bulk many instances at the same time is more efficient for a number of reasons
branching predictability CPU cache linear algebra libraries optimizations etc Here we see on a setting with few
features that independently of estimator choice the bulk mode is always faster and for some of them by 1 to 2 orders
of magnitude

654 Chapter 3 User Guide

scikitlearn user guide Release 0213

To benchmark different estimators for your case you can simply change the nfeatures parameter in this example
Prediction Latency This should give you an estimate of the order of magnitude of the prediction latency

Configuring Scikitlearn for reduced validation overhead

Scikitlearn does some validation on data that increases the overhead per call to predict and similar functions
In particular checking that features are finite not NaN or infinite involves a full pass over the data If you en
sure that your data is acceptable you may suppress checking for finiteness by setting the environment variable
SKLEARNASSUMEFINITE to a nonempty string before importing scikitlearn or configure it in Python with
sklearnsetconfig For more control than these global settings a configcontext allows you to set this
configuration within a specified context

```
import sklearn
with sklearnconfigcontextassumefinite True
pass do learningprediction here with reduced validation
```

Note that this will affect all uses of sklearnutilsassertallfinite within the context

Influence of the Number of Features

Obviously when the number of features increases so does the memory consumption of each example Indeed for a
matrix of ninstances with nfeatures the space complexity is in $O(n^2)$ From a computing perspective it also
means that the number of basic operations eg multiplications for vectormatrix products in linear models increases
too Here is a graph of the evolution of the prediction latency with the number of features

37 Computing with scikitlearn 655

scikitlearn user guide Release 0213

Overall you can expect the prediction time to increase at least linearly with the number of features nonlinear cases can happen depending on the global memory footprint and estimator

Influence of the Input Data Representation

Scipy provides sparse matrix data structures which are optimized for storing sparse data The main feature of sparse formats is that you don't store zeros so if your data is sparse then you use much less memory A nonzero value in a sparse CSR (Compressed Sparse Row) or CSC representation will only take on average one 32bit integer position the 64 bit floating point value an additional 32bit per row or column in the matrix Using sparse input on a dense or sparse linear model can speedup prediction by quite a bit as only the non zero valued features impact the dot product and thus the model predictions Hence if you have 100 non zeros in 1e6 dimensional space you only need 100 multiply and add operation instead of 1e6

Calculation over a dense representation however may leverage highly optimised vector operations and multithreading in BLAS and tends to result in fewer CPU cache misses So the sparsity should typically be quite high 10 nonzeros max to be checked depending on the hardware for the sparse input representation to be faster than the dense input representation on a machine with many CPUs and an optimized BLAS implementation

Here is sample code to test the sparsity of your input

```
def sparsity_ratio(X):
    return 10 * np.count_nonzero(X) / float(X.shape[0] * X.shape[1])
print(input_sparsity_ratio(sparsity_ratio(X)))
```

As a rule of thumb you can consider that if the sparsity ratio is greater than 90 you can probably benefit from sparse formats Check Scipy's sparse matrix formats documentation for more information on how to build or convert your data to sparse matrix formats Most of the time the CSR (Compressed Sparse Row) and CSC formats work best

scikitlearn user guide Release 0.21.3

Influence of the Model Complexity

Generally speaking when model complexity increases predictive power and latency are supposed to increase. Increasing predictive power is usually interesting but for many applications we would better not increase prediction latency too much. We will now review this idea for different families of supervised models.

For sklearn.linear_model, e.g. Lasso, ElasticNet, SGDClassifier, Regressor, Ridge, RidgeClassifier, PassiveAggressiveClassifier, Regressor, LinearSVC, LogisticRegression, the decision function that is applied at prediction time is the same as a dot product, so latency should be equivalent.

Here is an example using sklearn.linear_model.StochasticGradientDescentClassifier with the elasticnet penalty. The regularization strength is globally controlled by the alpha parameter. With a sufficiently high alpha, one can then increase the l1_ratio parameter of elasticnet to enforce various levels of sparsity in the model coefficients. Higher sparsity here is interpreted as less model complexity as we need fewer coefficients to describe it fully. Of course sparsity influences in turn the prediction time as the sparse dot product takes time roughly proportional to the number of nonzero coefficients.

For the sklearn.svm family of algorithms with a nonlinear kernel, the latency is tied to the number of support vectors: the fewer, the faster. Latency and throughput should asymptotically grow linearly with the number of support vectors in a SVC (Support Vector Classification) or SVR (Support Vector Regression) model. The kernel will also influence the latency as it is a projection of the input vector once per support vector. In the following graph, the nu parameter of sklearn.svm.SVC was used to influence the number of support vectors.

3.7 Computing with scikitlearn 657

scikitlearn user guide Release 0213

For sklearnensemble of trees eg RandomForest GBT ExtraTrees etc the number of trees and their depth play the most important role Latency and throughput should scale linearly with the number of trees In this case we used directly the nestimators parameter of sklearnensemblegradientboosting

GradientBoostingRegressor

In any case be warned that decreasing model complexity can hurt accuracy as mentioned above For instance a non linearly separable problem can be handled with a speedy linear model but prediction power will very likely suffer in the process

658 Chapter 3 User Guide

scikitlearn user guide Release 0213

Feature Extraction Latency

Most scikitlearn models are usually pretty fast as they are implemented either with compiled Cython extensions or optimized computing libraries On the other hand in many real world applications the feature extraction process ie turning raw data like database rows or network packets into numpy arrays governs the overall prediction time For example on the Reuters text classification task the whole preparation reading and parsing SGML files tokenizing the text and hashing it into a common vector space is taking 100 to 500 times more time than the actual prediction code depending on the chosen model

In many cases it is thus recommended to carefully time and profile your feature extraction code as it may be a good place to start optimizing when your overall latency is too slow for your application

Prediction Throughput

Another important metric to care about when sizing production systems is the throughput ie the number of predictions you can make in a given amount of time Here is a benchmark from the Prediction Latency example that measures this quantity for a number of estimators on synthetic data

37 Computing with scikitlearn 659

scikitlearn user guide Release 0213

These throughputs are achieved on a single process An obvious way to increase the throughput of your application is to spawn additional instances usually processes in Python because of the GIL that share the same model One might also add machines to spread the load A detailed explanation on how to achieve this is beyond the scope of this documentation though

Tips and Tricks

Linear algebra libraries

As scikitlearn relies heavily on NumpyScipy and linear algebra in general it makes sense to take explicit care of the versions of these libraries Basically you ought to make sure that Numpy is built using an optimized BLAS LAPACK library

Not all models benefit from optimized BLAS and Lapack implementations For instance models based on randomized decision trees typically do not rely on BLAS calls in their inner loops nor do kernel SVMs SVCSVRNuSVC NuSVR On the other hand a linear model implemented with a BLAS DGEMM call via numpydot will typically benefit hugely from a tuned BLAS implementation and lead to orders of magnitude speedup over a nonoptimized BLAS

You can display the BLAS LAPACK implementation used by your NumPy SciPy scikitlearn install with the following commands

```
from numpydistutilssysteminfo import getinfo
printgetinfoblasopt
printgetinfo lapackopt
```

Optimized BLAS LAPACK implementations include

- Atlas need hardware specific tuning by rebuilding on the target machine

scikitlearn user guide Release 0213

- OpenBLAS
- MKL
- Apple Accelerate and vecLib frameworks OSX only

More information can be found on the Scipy install page and in this blog post from Daniel Nouri which has some nice step by step install instructions for Debian Ubuntu

Limiting Working Memory

Some calculations when implemented using standard numpy vectorized operations involve using a large amount of temporary memory This may potentially exhaust system memory Where computations can be performed in fixed memory chunks we attempt to do so and allow the user to hint at the maximum size of this working memory defaulting to 1GB using sklearn.set_config or config_context The following suggests to limit temporary working memory to 128 MiB

```
import sklearn
with sklearn.config_context(working_memory=128):
    pass # do chunked work here
```

An example of a chunked operation adhering to this setting is metric.pairwise_distances_chunked which facilitates computing rowwise reductions of a pairwise distance matrix

Model Compression

Model compression in scikitlearn only concerns linear models for the moment In this context it means that we want to control the model sparsity ie the number of nonzero coordinates in the model vectors It is generally a good idea to combine model sparsity with sparse input data representation

Here is sample code that illustrates the use of the sparsify method

```
clf = SGDRegressor(penalty='elasticnet', l1_ratio=0.25)
clf.fit(X_train, y_train)
clf.predict(X_test)
```

In this example we prefer the elasticnet penalty as it is often a good compromise between model compactness and prediction power One can also further tune the l1_ratio parameter in combination with the regularization strength alpha to control this tradeoff

A typical benchmark on synthetic data yields a 30% decrease in latency when both the model and input are sparse with 0.000024 and 0.027400 nonzero coefficients ratio respectively Your mileage may vary depending on the sparsity and size of your data and model Furthermore sparsifying can be very useful to reduce the memory usage of predictive models deployed on production servers

Model Reshaping

Model reshaping consists in selecting only a portion of the available features to fit a model In other words if a model discards features during the learning phase we can then strip those from the input This has several benefits Firstly it reduces memory and therefore time overhead of the model itself It also allows to discard explicit feature selection components in a pipeline once we know which features to keep from a previous run Finally it can help reduce processing time and IO usage upstream in the data access and feature extraction layers by not collecting and building features that are discarded by the model For instance if the raw data come from a database it can make it possible to write simpler and faster queries or reduce IO usage by making the queries return lighter records At the 37 Computing with scikitlearn 661

scikitlearn user guide Release 0213

moment reshaping needs to be performed manually in scikitlearn In the case of sparse input particularly in CSR (Compressed Sparse Row) format it is generally sufficient to not generate the relevant features leaving their columns empty

373 Parallelism resource management and configuration

Parallel and distributed computing

Scikitlearn uses the joblib library to enable parallel computing inside its estimators See the joblib documentation for the switches to control parallel computing

Note that by default scikitlearn uses its embedded vendored version of joblib A configuration switch documented below controls this behavior

Configuration switches

Python runtime

sklearnsetconfig controls the following behaviors

assumefinite used to skip validation which enables faster computations but may lead to segmentation faults if the data contains NaNs

workingmemory the optimal size of temporary arrays used by some algoritms

Environment variables

These environment variables should be set before importing scikitlearn

SKLEARNSITEJOBLIB When this environment variable is set to a non zero value scikitlearn uses the site joblib rather than its vendored version Consequently joblib must be installed for scikitlearn to run Note that using the site joblib is at your own risks the versions of scikitlearn and joblib need to be compatible Currently joblib 011 is supported In addition dumps from joblibMemory might be incompatible and you might loose some caches and have to redownload some datasets

Deprecated since version 021 As of version 021 this parameter has no effect vendored joblib was removed and site joblib is always used

SKLEARNASSUMEFINITE Sets the default value for the assumefinite argument of sklearnsetconfig

SKLEARNWORKINGMEMORY Sets the default value for the Limiting Working Memory argument ofsklearnsetconfig

SKLEARNSEED Sets the seed of the global random generator when running the tests for reproducibility

SKLEARNSKIPNETWORKTESTS When this environment variable is set to a non zero value the tests that need network access are skipped

662 Chapter 3 User Guide

CHAPTER

FOUR

GLOSSARY OF COMMON TERMS AND API (Application Programming Interface) ELEMENTS

This glossary hopes to definitively represent the tacit and explicit conventions applied in Scikitlearn and its API (Application Programming Interface) providing a reference for users and contributors It aims to describe the concepts and either detail their corresponding API (Application Programming Interface) or link to other relevant parts of the documentation which do so By linking to glossary entries from the API Reference and User Guide we may minimize redundancy and inconsistency

We begin by listing general concepts and any that didn't fit elsewhere but more specific sets of related terms are listed below Class APIs and Estimator Types Target Types Methods Parameters Attributes Data and sample properties

41 General Concepts

1d

1d array Onedimensional array A NumPy array whose shape has length 1 A vector

2d

2d array Twodimensional array A NumPy array whose shape has length 2 Often represents a matrix

API (Application Programming Interface) Refers to both the specific interfaces for estimators implemented in Scikitlearn and the generalized conventions across types of estimators as described in this glossary and overviewed in the contributor documentation

The specific interfaces that constitute Scikitlearn's public API (Application Programming Interface) are largely documented in API (Application Programming Interface) ever we less formally consider anything as public API (Application Programming Interface) if none of the identifiers required to access it begins with an underscore

We generally try to maintain backwards compatibility for all objects in the public API (Application Programming Interface)

Private API (Application Programming Interface) including functions modules and methods beginning with an underscore are not assured to be stable

arraylike The most common data format for input to Scikitlearn estimators and functions arraylike is any type that supports the `__getitem__` and `__len__` methods

object for which `numpy.asarray` will produce an array of appropriate shape usually 1 or 2dimensional of appropriate dtype usually numeric

This includes

- a numpy array
- a list of numbers
- a list of lengthk lists of numbers for some fixed length k
- a pandasDataFrame with all columns numeric
- a numeric pandasSeries

It excludes

- a sparse matrix
- an iterator

scikitlearn user guide Release 0213

- a generator

Note that output from scikitlearn estimators and functions eg predictions should generally be arrays or sparse matrices or lists thereof as in multioutput treeDecisionTreeClassifier 'spredictproba An estimator where predict returns a list or a pandasSeries is not valid

attribute

attributes We mostly use attribute to refer to how model information is stored on an estimator during fitting Any public attribute stored on an estimator instance is required to begin with an alphabetic character and end in a single underscore if it is set in fitorpartialfit These are what is documented under an estimator's Attributes documentation The information stored in attributes is usually either sufficient statistics used for prediction or transformation transductive outputs such as labels orembedding or diagnostic data such as featureimportances Common attributes are listed below

A public attribute may have the same name as a constructor parameter with a appended This is used to store a validated or estimated version of the user's input For example decompositionPCA is constructed with anncomponents parameter From this together with other parameters and the data PCA (Principal Component Analysis) estimates the attributencomponents

Further private attributes used in predictiontransformationetc may also be set when fitting These begin with a single underscore and are not assured to be stable for public access

A public attribute on an estimator instance that does not end in an underscore should be the stored unmodified value of an init parameter of the same name Because of this equivalence these are documented under an estimator's Parameters documentation

backwards compatibility We generally try to maintain backwards compatibility ie interfaces and behaviors may be extended but not changed or removed from release to release but this comes with some exceptions

Public API (Application Programming Interface) only The behaviour of objects accessed through private identifiers those beginning may be changed arbitrarily between versions

As documented We will generally assume that the users have adhered to the documented parameter types and ranges If the documentation asks for a list and the user gives a tuple we do not assure consistent behavior from version to version

Deprecation Behaviors may change following a deprecation period usually two releases long Warnings are issued using Python's warnings module

Keyword arguments We may sometimes assume that all optional parameters other than X and y to fitand similar methods are passed as keyword arguments only and may be positionally reordered

Bug fixes and enhancements Bug fixes and - less often - enhancements may change the behavior of estimators including the predictions of an estimator trained on the same data and randomstate When this happens we attempt to note it clearly in the changelog

Serialization We make no assurances that pickling an estimator in one version will allow it to be unpickled to an equivalent model in the subsequent version For estimators in the sklearn package we issue a warning when this unpickling is attempted even if it may happen to work See Security maintainability limitations

utilsestimatorcheckscheckestimator We provide limited backwards compatibility assurances for the estimator checks we may add extra requirements on estimators tested with this function usually when these were informally assumed but not formally tested

Despite this informal contract with our users the software is provided as is as stated in the licence When a release inadvertently introduces changes that are not backwards compatible these are known as software regressions

callable A function class or an object which implements the call method anything that returns True when the argument of callable

scikitlearn user guide Release 0213

categorical feature A categorical or nominal feature is one that has a finite set of discrete values across the population of data These are commonly represented as columns of integers or strings Strings will be rejected by most scikitlearn estimators and integers will be treated as ordinal or countvalued For the use with most estimators categorical variables should be onehot encoded Notable exceptions include treebased models such as random forests and gradient boosting models that often work better and faster with integercoded categorical variables OrdinalEncoder helps encoding stringvalued categorical features as ordinal integers and OneHotEncoder can be used to onehot encode categorical features See also Encoding categorical features and the categoricalencoding package for tools related to encoding categorical features

clone

cloned To copy an estimator instance and create a new one with identical parameters but without any fitted attributes usingclone

Whenfit is called a metaestimator usually clones a wrapped estimator instance before fitting the cloned instance Exceptions for legacy reasons include Pipeline andFeatureUnion

common tests This refers to the tests run on almost every estimator class in Scikitlearn to check they comply with basic API (Application Programming Interface) conventions They are available for external use through utilsestimatorchecks checkestimator with most of the implementation in sklearnutilsestimatorcheckspy

Note Some exceptions to the common testing regime are currently hardcoded into the library but we hope to replace this by marking exceptional behaviours on the estimator using semantic estimator tags

deprecation We use deprecation to slowly violate our backwards compatibility assurances usually to to

- change the default value of a parameter or
- remove a parameter attribute method class etc

We will ordinarily issue a warning when a deprecated element is used although there may be limitations to this

For instance we will raise a warning when someone sets a parameter that has been deprecated but may not when they access that parameter's attribute on the estimator instance

See the Contributors' Guide

dimensionality May be used to refer to the number of features ie nfeatures or columns in a 2d feature matrix Dimensions are however also used to refer to the length of a NumPy array's shape distinguishing a 1d array from a 2d matrix

docstring The embedded documentation for a module class function etc usually in code as a string at the beginning of the object's definition and accessible as the object's doc attribute

We try to adhere to PEP257 and follow NumpyDoc conventions

double underscore

double underscore notation When specifying parameter names for nested estimators may be used to separate between parent and child in some contexts The most common use is when setting parameters through a meta estimator with setparams and hence in specifying a search grid in parameter search See parameter It is also used inpipelinePipelinefit for passing sample properties to thefit methods of estimators in the

pipeline

dtype

data type NumPy arrays assume a homogeneous data type throughout available in the dtype attribute of an array or sparse matrix We generally assume simple data types for scikitlearn data float or integer We may support object or string data types for arrays before encoding or vectorizing Our estimators do not work with struct arrays for instance

TODO Mention efficiency and precision issues casting policy

41 General Concepts 665

scikitlearn user guide Release 0213

duck typing We try to apply duck typing to determine how to handle some input values eg checking whether a given estimator is a classifier That is we avoid using isinstance where possible and rely on the presence or absence of attributes to determine an object’s behaviour Some nuance is required when following this approach

- For some estimators an attribute may only be available once it is fitted For instance we cannot a priori determine if predict_proba is available in a grid search where the grid includes alternating between a probabilistic and a nonprobabilistic predictor in the final step of the pipeline In the following we can only determine if clf is probabilistic after fitting it on some data

```
from sklearn.model_selection import GridSearchCV
from sklearn.linear_model import SGDClassifier
clf = GridSearchCV(SGDClassifier(
    param_grid=dict(loss=log, hinge=
```

This means that we can only check for ducktyped attributes after fitting and that we must be careful to make metaestimators only present attributes according to the state of the underlying estimator after fitting

- Checking if an attribute is present using hasattr is in general just as expensive as getting the attribute getattr or dot notation In some cases getting the attribute may indeed be expensive eg for some implementations of feature importances which may suggest this is an API (Application Programming Interface) design flaw So code which does hasattr followed by getattr should be avoided getattr within a tryexcept block is preferred

- For determining some aspects of an estimator’s expectations or support for some feature we use estimator tags instead of duck typing

early stopping This consists in stopping an iterative optimization method before the convergence of the training loss to avoid overfitting This is generally done by monitoring the generalization score on a validation set When available it is activated through the parameter early_stopping or by setting a positive n_iter_no_change estimator instance We sometimes use this terminology to distinguish an estimator class from a constructed instance For example in the following cls is an estimator class while est1 and est2 are instances

```
cls = RandomForestClassifier
est1 = cls
est2 = RandomForestClassifier
```

examples We try to give examples of basic usage for most functions and classes in the API (Application Programming Interface)

- as doctests in their docstrings ie within the sklearn library code itself
- as examples in the example gallery rendered using sphinx_gallery from scripts in the examples directory exemplifying key features or parameters of the estimator/function These should also be referenced from the User Guide

- sometimes in the User Guide built from doc alongside a technical description of the estimator evaluation metric

evaluation metrics Evaluation metrics give a measure of how well a model performs We may use this term specifically to refer to the functions in metrics disregarding metrics pairwise as distinct from the score method and the scoring API (Application Programming Interface) used in cross validation See Model evaluation quantifying the quality of predictions

These functions usually accept a ground truth or the raw data where the metric evaluates clustering without a ground truth and a prediction be it the output of predict ypred of predict_proba yproba or of an arbitrary score function including decisionfunction yscore Functions are usually named to end with score if a greater score indicates a better model and loss if a lesser score indicates a better model This diversity of interface motivates the scoring API (Application Programming Interface)

scikitlearn user guide Release 0213

Note that some estimators can calculate metrics that are not included in metrics and are estimatorspecific notably model likelihoods

estimator tags A proposed feature eg 8022 by which the capabilities of an estimator are described through a set of semantic tags This would enable some runtime behaviors based on estimator inspection but it also allows each estimator to be tested for appropriate invariances while being excepted from other common tests Some aspects of estimator tags are currently determined through the duck typing of methods like predictproba and through some special attributes on estimator objects

estimatortype This stringvalued attribute identifies an estimator as being a classifier regressor etc It is set by mixins such as baseClassifierMixin but needs to be more explicitly adopted on a meta estimator Its value should usually be checked by way of a helper such as baseisclassifier pairwise This boolean attribute indicates whether the data X passed tofit and similar methods consists of pairwise measures over samples rather than a feature representation for each sample It is usually True where an estimator has a metric oraffinity orkernel parameter with value 'precomputed' Its primary purpose is that when a metaestimator extracts a subsample of data intended for a pairwise estimator the data needs to be indexed on both axes while other data is indexed only on the first axis

feature

features

feature vector In the abstract a feature is a function in its mathematical sense mapping a sampled object to a numeric or categorical quantity "Feature" is also commonly used to refer to these quantities being the individual elements of a vector representing a sample In a data matrix features are represented as columns each column contains the result of applying a feature function to a set of samples

Elsewhere features are known as attributes predictors regressors or independent variables

Nearly all estimators in scikitlearn assume that features are numeric finite and not missing even when they have semantically distinct domains and distributions categorical ordinal countvalued realvalued interval See also categorical feature andmissing values

nfeatures indicates the number of features in a dataset

fitting Calling fitforfittransform fitpredict etc on an estimator

fitted The state of an estimator after fitting

There is no conventional procedure for checking if an estimator is fitted However an estimator that is not fitted

- should raise exceptionsNotFittedError when a prediction method predict transform etc is

called utilvalidationcheckisfitted is used internally for this purpose

- should not have any attributes beginning with an alphabetic character and ending with an underscore

Note that a descriptor for the attribute may still be present on the class but hasattr should return False

function We provide ad hoc function interfaces for many algorithms while estimator classes provide a more consistent interface

In particular Scikitlearn may provide a function interface that fits a model to some data and returns the learnt

model parameters as in linearmodelenetpath For transductive models this also returns the em

bedding or cluster labels as in manifoldspectralembedding orclusterdbscan Many prepro

cessing transformers also provide a function interface akin to calling fittransform as inpreprocessing

maxabsscale Users should be careful to avoid data leakage when making use of these fittransform

equivalent functions

We do not have a strict policy about when to or when not to provide function forms of estimators but maintainers should consider consistency with existing interfaces and whether providing a function would lead users astray

from best practices as regards data leakage etc

41 General Concepts 667

scikitlearn user guide Release 0213
gallery Seeexamples
hyperparameter
hyperparameter Seeparameter
impute
imputation Most machine learning algorithms require that their inputs have no missing values and will not work if this requirement is violated Algorithms that attempt to fill in or impute missing values are referred to as imputation algorithms
indexable Anarraylike sparse matrix pandas DataFrame or sequence usually a list
induction
inductive Inductive contrasted with transductive machine learning builds a model of some data that can then be applied to new instances Most estimators in Scikitlearn are inductive having predict and/or transform methods
joblib A Python library <https://joblib.readthedocs.io> used in Scikitlearn to facilitate simple parallelism and caching
Joblib is oriented towards efficiently working with numpy arrays such as through use of memory mapping See Parallel and distributed computing for more information
label indicator matrix
multilabel indicator matrix
multilabel indicator matrices The format used to represent multilabel data where each row of a 2d array or sparse matrix corresponds to a sample each column corresponds to a class and each element is 1 if the sample is labeled with the class and 0 if not
leakage
data leakage A problem in cross validation where generalization performance can be overestimated since knowledge of the test data was inadvertently included in training a model This is a risk for instance when applying a transformer to the entirety of a dataset rather than each training portion in a cross validation split
We aim to provide interfaces such as pipeline and model selection that shield the user from data leakage
memmapping
memory map
memory mapping A memory efficiency strategy that keeps data on disk rather than copying it into main memory
Memory maps can be created for arrays that can be read written or both using `numpy.memmap` When using joblib to parallelize operations in Scikitlearn it may automatically memmap large arrays to reduce memory duplication overhead in multiprocessing
missing values Most Scikitlearn estimators do not work with missing values When they do eg in `SimpleImputer` `NaN` is the preferred representation of missing values in float arrays If the array has integer dtype `NaN` cannot be represented For this reason we support specifying another missing values value when imputation or learning can be performed in integer space Unlabeled data is a special case of missing values in the target
`nfeatures` The number of features
`noutputs` The number of outputs in the target
`nsamples` The number of samples
`ntargets` Synonym for `noutputs`
narrative docs
668 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

narrative documentation An alias for User Guide ie documentation written in docmodules Unlike the API (Application Programming Interface) reference provided through docstrings the User Guide aims to

- group tools provided by Scikitlearn together thematically or in terms of usage
- motivate why someone would use each particular tool often through comparison
- provide both intuitive and technical descriptions of tools
- provide or link to examples of using key features of a tool

npA shorthand for Numpy due to the conventional import statement

import numpy as np

online learning Where a model is iteratively updated by receiving each batch of ground truth targets soon after making predictions on corresponding batch of data Intrinsically the model must be usable for prediction after each batch See partialfit

outofcore An efficiency strategy where not all the data is stored in main memory at once usually by performing learning on batches of data See partialfit

outputs Individual scalarcategorical variables per sample in the target For example in multilabel classification each possible label corresponds to a binary output Also called responses tasks ortargets See multiclass multioutput andcontinuous multioutput

pair A tuple of length two

parameter

parameters

param

params We mostly use parameter to refer to the aspects of an estimator that can be specified in its construction For examplemaxdepth andrandomstate are parameters of RandomForestClassifier Parameters

to an estimator’s constructor are stored unmodified as attributes on the estimator instance and conventionally start with an alphabetic character and end with an alphanumeric character Each estimator’s constructor parameters are described in the estimator’s docstring

We do not use parameters in the statistical sense where parameters are values that specify a model and can be estimated from data What we call parameters might be what statisticians call hyperparameters to the model aspects for configuring model structure that are often not directly learnt from data However our parameters are also used to prescribe modeling operations that do not affect the learnt model such as njobs for controlling parallelism

When talking about the parameters of a metaestimator we may also be including the parameters of the estimators wrapped by the metaestimator Ordinarily these nested parameters are denoted by using adouble underscore to separate between the estimatorasparameter and its parameter Thus clf

BaggingClassifierbaseestimatorDecisionTreeClassifiermaxdepth3 has

a deep parameter baseestimatormaxdepth with value 3 which is accessible with clf

baseestimatormaxdepth orclfgetparamsbaseestimatormaxdepth

The list of parameters and their current values can be retrieved from an estimator instance using its getparams method

Between construction and fitting parameters may be modified using setparams To enable this parameters are not ordinarily validated or altered when the estimator is constructed or when each parameter is set Parameter validation is performed when fitis called

Common parameters are listed below

pairwise metric

41 General Concepts 669

scikitlearn user guide Release 0213

pairwise metrics In its broad sense a pairwise metric defines a function for measuring similarity or dissimilarity between two samples with each ordinarily represented as a feature vector We particularly provide implementations of distance metrics as well as improper metrics like Cosine Distance through metrics pairwise_distances and of kernel functions a constrained class of similarity functions in metrics pairwise_kernels These can compute pairwise distance matrices that are symmetric and hence store data redundantly

See also precomputed and metric

Note that for most distance metrics we rely on implementations from scipy.spatial.distance but may reimplement for efficiency in our context The neighbors module also duplicates some metric implementations for integration with efficient binary tree search data structures

pdA shorthand for Pandas due to the conventional import statement

import pandas as pd

precomputed Where algorithms rely on pairwise metrics and can be computed from pairwise metrics alone we often allow the user to specify that the X provided is already in the pairwise dissimilarity space rather than in a feature space That is when passed to fit it is a square symmetric matrix with each vector indicating dissimilarity to every sample and when passed to prediction transformation methods each row corresponds to a testing sample and each column to a training sample

Use of precomputed X is usually indicated by setting a metric affinity or kernel parameter to the string 'precomputed' An estimator should mark itself as being pairwise if this is the case rectangular Data that can be represented as a matrix with samples on the first axis and a fixed finite set of features on the second is called rectangular

This term excludes samples with nonvectorial structure such as text an image of arbitrary size a time series of arbitrary length a set of vectors etc The purpose of a vectorizer is to produce rectangular forms of such data sample

samples We usually use this term as a noun to indicate a single feature vector Elsewhere a sample is called an instance data point or observation nsamples indicates the number of samples in a dataset being the number of rows in a data array X

sample property

sample properties A sample property is data for each sample eg an array of length nsamples passed to an estimator method or a similar function alongside but distinct from the features X and target y The most prominent example is sample_weight see others at Data and sample properties

As of version 019 we do not have a consistent approach to handling sample properties and their routing in metaestimators though a fit_params parameter is often used

scikitlearncontrib A venue for publishing Scikitlearncompatible libraries that are broadly authorized by the core developers and the contrib community but not maintained by the core developer team See https

scikitlearncontribgithubio

scikitlearn enhancement proposals

SLEP

SLEPs Changes to the API (Application Programming Interface) principles and changes to dependencies or supported versions happen via a SLEP and

follows the decisionmaking process outlined in Scikitlearn governance and decisionmaking For all votes a proposal must have been made public and discussed before the vote Such proposal must be a consolidated document in the form of a 'ScikitLearn Enhancement Proposal' SLEP rather than a long discussion on an issue A SLEP must be submitted as a pullrequest to enhancement proposals using the SLEP template

semisupervised

670 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

semisupervised learning

semisupervised Learning where the expected prediction label or ground truth is only available for some samples provided as training data when fitting the model We conventionally apply the label 1 to unlabeled samples in semisupervised classification

sparse matrix A representation of two dimensional numeric data that is more memory efficient than the corresponding dense numpy array where almost all elements are zero We use the scipy sparse framework which provides several underlying sparse data representations or formats Some formats are more efficient than others for particular tasks and when a particular format provides especial benefit we try to document this fact in Scikit learn parameter descriptions

Some sparse matrix formats notably CSR (Compressed Sparse Row) CSC COO and LIL distinguish between implicit and explicit zeros Explicit zeros are stored ie they consume memory in a data array in the data structure while implicit zeros correspond to every element not otherwise defined in explicit storage

Two semantics for sparse matrices are used in Scikit learn

matrix semantics The sparse matrix is interpreted as an array with implicit and explicit zeros being interpreted as the number 0 This is the interpretation most often adopted eg when sparse matrices are used for feature matrices or multilabel indicator matrices

graph semantics As with scipy sparse csrgraph explicit zeros are interpreted as the number 0 but implicit zeros indicate a masked or absent value such as the absence of an edge between two vertices of a graph where an explicit value indicates an edge's weight This interpretation is adopted to represent connectivity in clustering in representations of nearest neighborhoods eg neighbors kneighborsgraph and for precomputed distance representation where only distances in the neighborhood of each point are required

When working with sparse matrices we assume that it is sparse for a good reason and avoid writing code that densifies a user provided sparse matrix instead maintaining sparsity or raising an error if not possible ie if an estimator does not cannot support sparse matrices

supervised

supervised learning Learning where the expected prediction label or ground truth is available for each sample when fitting the model provided as y This is the approach taken in a classifier or regressor among other estimators

target

targets The dependent variable in supervised and semisupervised learning passed as y to an estimator's fit method Also known as dependent variable outcome variable response variable ground truth or label Scikit learn works with targets that have minimal structure a class from a finite set a finite real valued number multiple classes or multiple numbers See Target Types

transduction

transductive A transductive contrasted with inductive machine learning method is designed to model a specific dataset but not to apply that model to unseen data Examples include manifold TSNE cluster Agglomerative Clustering and neighbors Local Outlier Factor

unlabeled

unlabeled data Samples with an unknown ground truth when fitting equivalently missing values in the target See also semisupervised and unsupervised learning

unsupervised

unsupervised learning Learning where the expected prediction label or ground truth is not available for each sample when fitting the model as in clusterers and outlier detectors Unsupervised estimators ignore any y passed to fit

42 Class APIs and Estimator Types

classifier

classifiers A supervised or semi-supervised predictor with a finite set of discrete possible output values

A classifier supports modeling some of binary multiclass multilabel or multiclass multioutput targets Within scikitlearn all classifiers support multiclass classification defaulting to using a one-vs-rest strategy over the binary classification problem

Classifiers must store a classes attribute after fitting and usually inherit from baseClassifierMixin

which sets their estimator_type attribute

A classifier can be distinguished from other estimators with is_classifier

A classifier must implement

- fit
- predict
- score

It may also be appropriate to implement decision_function predict_proba and predict_log_proba

clusterer

clusterers An unsupervised predictor with a finite set of discrete output values

A clusterer usually stores labels after fitting and must do so if it is transductive

A clusterer must implement

- fit
- fit_predict if transductive
- predict if inductive

density estimator TODO

estimator

estimators An object which manages the estimation and decoding of a model The model is estimated as a deterministic function of

- parameters provided in object construction or with set_params
- the global numpy.random random state if the estimator's random_state parameter is set to None and
- any data or sample properties passed to the most recent call to fit fit_transform or fit_predict or data

similarly passed in a sequence of calls to partial_fit

The estimated model is stored in public and private attributes on the estimator instance facilitating decoding through prediction and transformation methods

Estimators must provide a fit_method and should provide set_params and get_params although these are usually provided by inheritance from baseBaseEstimator

The core functionality of some estimators may also be available as a function

feature extractor

feature extractors A transformer which takes input where each sample is not represented as an arraylike object of fixed length and produces an arraylike object of features for each sample and thus a 2-dimensional arraylike for a set of samples In other words it lossily maps a nonrectangular data representation into rectangular data

scikitlearn user guide Release 0213

Feature extractors must implement at least

- fit
- transform
- getfeaturenames

metaestimator

metaestimators

metaestimator

metaestimators Anestimator which takes another estimator as a parameter Examples include pipeline

Pipeline modelselectionGridSearchCV featureselectionSelectFromModel and

ensembleBaggingClassifier

In a metaestimator’s fitmethod any contained estimators should be cloned before they are fit although FIXME

Pipeline and FeatureUnion do not do this currently An exception to this is that an estimator may explic

itly document that it accepts a prefitted estimator eg using prefitTrue infeatureselection

SelectFromModel One known issue with this is that the prefitted estimator will lose its model if the

metaestimator is cloned A metaestimator should have fit called before prediction even if all contained

estimators are prefitted

In cases where a metaestimator’s primary behaviors eg predict ortransform implementation are functions

of predictiontransformation methods of the provided base estimator or multiple base estimators a meta

estimator should provide at least the standard methods provided by the base estimator It may not be possible

to identify which methods are provided by the underlying estimator until the metaestimator has been fitted

see also duck typing for which utilsmetaestimatorsifdelegatehasmethod may help It

should also provide or modify the estimator tags andclasses attribute provided by the base estimator

Metaestimators should be careful to validate data as minimally as possible before passing it to an underlying

estimator This saves computation time and may for instance allow the underlying estimator to easily work

with data that is not rectangular

outlier detector

outlier detectors Anunsupervised binary predictor which models the distinction between core and outlying samples

Outlier detectors must implement

- fit
- fitpredict iftransductive
- predict ifinductive

Inductive outlier detectors may also implement decisionfunction to give a normalized inlier score where outliers

have score below 0 scoresamples may provide an unnormalized score per sample

predictor

predictors Anestimator supporting predict andor fitpredict This encompasses classifier regressor outlier detec

torandclusterer

In statistics “predictors” refers to features

regressor

regressors Asupervised orsemisupervised predictor with continuous output values

Regressors usually inherit from baseRegressorMixin which sets their estimatortype attribute

A regressor can be distinguished from other estimators with isregressor

42 Class APIs and Estimator Types 673

scikitlearn user guide Release 0213

A regressor must implement

- fit
- predict
- score

transformer

transformers An estimator supporting transform and/or fit_transform A purely transductive transformer such as manifoldTSNE may not implement transform

vectorizer

vectorizers See feature extractor

There are further APIs specifically related to a small family of estimators such as

crossvalidation splitter

CV (Cross-Validation) splitter

crossvalidation generator A non-estimator family of classes used to split a dataset into a sequence of train and test portions see Crossvalidation evaluating estimator performance by providing split and get_n_splits methods

Note that unlike estimators these do not have fit methods and do not provide set_params or get_params

Parameter validation may be performed in init

crossvalidation estimator An estimator that has builtin crossvalidation capabilities to automatically select the best

hyperparameters see the User Guide Some example of crossvalidation estimators are ElasticNetCV and

LogisticRegressionCV Crossvalidation estimators are named EstimatorCV and tend to be roughly

equivalent to GridSearchCVEstimator The advantage of using a crossvalidation estimator

over the canonical Estimator class along with grid search is that they can take advantage of warmstarting

by reusing precomputed results in the previous steps of the crossvalidation process This generally leads to

speed improvements An exception is the RidgeCV class which can instead perform efficient LeaveOneOut

CV (Cross-Validation)

scorer A non-estimator callable object which evaluates an estimator on given test data returning a number Unlike

evaluation metrics a greater returned number must correspond with a better score See The scoring parameter

defining model evaluation rules

Further examples

- neighborsDistanceMetric
- gaussianprocesskernelsKernel
- treeCriterion

43 Target Types

binary A classification problem consisting of two classes A binary target may be represented as for a multiclass

problem but with only two labels A binary decision function is represented as a 1d array

Semantically one class is often considered the “positive” class Unless otherwise specified eg using pos_label

in evaluation metrics we consider the class label with the greater value numerically or lexicographically as

the positive class of labels 0 1 1 is the positive class of 1 2 2 is the positive class of ‘no’ ‘yes’ ‘yes’

is the positive class of ‘no’ ‘YES’ ‘no’ is the positive class This affects the output of decision_function for

instance

Note that a dataset sampled from a multiclass y or a continuous y may appear to be binary

674 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

typeoftarget will return 'binary' for binary input or a similar array with only a single class present

continuous A regression problem where each sample's target is a finite floating point number represented as a 1dimensional array of floats or sometimes ints

typeoftarget will return 'continuous' for continuous input but if the data is all integers it will be identified as 'multiclass'

continuous multioutput

multioutput continuous A regression problem where each sample's target consists of noutputs outputs each one a finite floating point number for a fixed int noutputs 1 in a particular dataset

Continuous multioutput targets are represented as multiple continuous targets horizontally stacked into an array of shapensamples noutputs

typeoftarget will return 'continuousmultioutput' for continuous multioutput input but if the data is all integers it will be identified as 'multiclassmultioutput'

multiclass A classification problem consisting of more than two classes A multiclass target may be represented as a 1dimensional array of strings or integers A 2d column vector of integers ie a single output in multioutput terms is also accepted

We do not officially support other orderable hashable objects as class labels even if estimators may happen to work when given classification targets of such type

For semisupervised classification unlabeled samples should have the special label 1 in y

Within scikitlearn all estimators supporting binary classification also support multiclass classification using OnevsRest by default

ApreprocessingLabelEncoder helps to canonicalize multiclass targets as integers

typeoftarget will return 'multiclass' for multiclass input The user may also want to handle 'binary' input identically to 'multiclass'

multiclass multioutput

multioutput multiclass A classification problem where each sample's target consists of noutputs outputs each a class label for a fixed int noutputs 1 in a particular dataset Each output has a fixed set of available classes and each sample is labelled with a class for each output An output may be binary or multiclass and in the case where all outputs are binary the target is multilabel

Multiclass multioutput targets are represented as multiple multiclass targets horizontally stacked into an array of shapensamples noutputs

XXX For simplicity we may not always support string class labels for multiclass multioutput and integer class labels should be used

multioutput provides estimators which estimate multioutput problems using multiple singleoutput estimators This may not fully account for dependencies among the different outputs which methods natively handling the multioutput case eg decision trees nearest neighbors neural networks may do better

typeoftarget will return 'multiclassmultioutput' for multiclass multioutput input

multilabel A multiclass multioutput target where each output is binary This may be represented as a 2d dense array or sparse matrix of integers such that each column is a separate binary target where positive labels are indicated with 1 and negative labels are usually 1 or 0 Sparse multilabel targets are not supported everywhere that dense multilabel targets are supported

Semantically a multilabel target can be thought of as a set of labels for each sample While not used internally preprocessingMultiLabelBinarizer is provided as a utility to convert from a list of sets

representation to a 2d array or sparse matrix Onehot encoding a multiclass target with preprocessing

LabelBinarizer turns it into a multilabel problem

43 Target Types 675

scikitlearn user guide Release 0213

typeoftarget will return ‘multilabelindicator’ for multilabel input whether sparse or dense

multioutput

multioutput A target where each sample has multiple classificationregression labels See multiclass multioutput

andcontinuous multioutput We do not currently support modelling mixed classification and regression targets

44 Methods

decisionfunction In a fitted classifier oroutlier detector predicts a “soft” score for each sample in relation to each class rather than the “hard” categorical prediction produced by predict Its input is usually only some

observed data X

If the estimator was not already fitted calling this method should raise a exceptionsNotFittedError

Output conventions

binary classification A 1dimensional array where values strictly greater than zero indicate the positive class

ie the last class in classes

multiclass classification A 2dimensional array where the rowwise argmaximum is the predicted class

Columns are ordered according to classes

multilabel classification Scikitlearn is inconsistent in its representation of multilabel decision functions

Some estimators represent it like multiclass multioutput ie a list of 2d arrays each with two columns

Others represent it with a single 2d array whose columns correspond to the individual binary classification

decisions The latter representation is ambiguously identical to the multiclass classification format though

its semantics differ it should be interpreted like in the binary case by thresholding at 0

TODO This gist highlights the use of the different formats for multilabel

multioutput classification A list of 2d arrays corresponding to each multiclass decision function

outlier detection A 1dimensional array where a value greater than or equal to zero indicates an inlier

fit Thefit method is provided on every estimator It usually takes some samplesXtargetsyif the model is

supervised and potentially other sample properties such as sampleweight It should

- clear any prior attributes stored on the estimator unless warmstart is used
- validate and interpret any parameters ideally raising an error if invalid
- validate the input data
- estimate and store model attributes from the estimated parameters and provided data and
- return the now fitted estimator to facilitate method chaining

Target Types describes possible formats for y

fitpredict Used especially for unsupervised transductive estimators this fits the model and returns the pre

dictions similar to predict on the training data In clusterers these predictions are also stored in the labels

attribute and the output of fitpredictX is usually equivalent to fitXpredictX The pa

rameters to fitpredict are the same as those to fit

fittransform A method on transformers which fits the estimator and returns the transformed training

data It takes parameters as in fitand its output should have the same shape as calling fitX

transformX There are nonetheless rare cases where fittransformX andfitX

transformX do not return the same value wherein training data needs to be handled differently due

to model blending in stacked ensembles for instance such cases should be clearly documented Transductive

transformers may also provide fittransform but not transform

676 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

One reason to implement `fit_transform` is that performing `fit` and `transform` separately would be less efficient than together `BaseTransformerMixin` provides a default implementation providing a consistent interface across transformers where `fit_transform` is or is not specialised

Inductive learning – where the goal is to learn a generalised model that can be applied to new data – users should be careful not to apply `fit_transform` to the entirety of a dataset ie training and test data together before further modelling as this results in data leakage

`get_feature_names` Primarily for feature extractors but also used for other transformers to provide string names for each column in the output of the estimator’s `transform` method It outputs a list of strings and may take a list of strings as input corresponding to the names of input columns from which output column names can be generated By default input features are named `x0` `x1`

`get_n_splits` On a CV (Cross-Validation) splitter not an estimator returns the number of elements one would get if iterating through the return value of `split` given the same parameters Takes the same parameters as `split`

`get_params` Gets all parameters and their values that can be set using `set_params` A parameter deep can be used when set to `False` to only return those parameters not including ie not due to indirection via contained estimators

Most estimators adopt the definition from `BaseEstimator` which simply adopts the parameters defined for `init` `Pipeline` among others reimplements `get_params` to declare the estimators named in its steps parameters as themselves being parameters

`partial_fit` Facilitates fitting an estimator in an online fashion Unlike `fit` repeatedly calling `partial_fit` does not clear the model but updates it with respect to the data provided The portion of data provided to `partial_fit` may be called a minibatch Each minibatch must be of consistent shape etc In iterative estimators `partial_fit` often only performs a single iteration

`partial_fit` may also be used for outofcore learning although usually limited to the case where learning can be performed online ie the model is usable after each `partial_fit` and there is no separate processing needed to finalize the model `cluster.Birch` introduces the convention that calling `partial_fit_X` will produce a model that is not finalized but the model can be finalized by calling `partial_fit` ie without passing a further minibatch

Generally estimator parameters should not be modified between calls to `partial_fit` although `partial_fit` should validate them as well as the new minibatch of data In contrast `warmstart` is used to repeatedly fit the same estimator with the same data but varying parameters

`LikeFitPartialFit` should return the estimator object

To clear the model a new estimator should be constructed for instance with `base.clone`

`predict` Makes a prediction for each sample usually only taking `X` as input but see under regressor output conventions below In a classifier or regressor this prediction is in the same target space used in fitting eg one of ‘red’ ‘amber’ ‘green’ if the yin fitting consisted of these strings Despite this even when y passed to `fit` is a list or other arraylike the output of `predict` should always be an array or sparse matrix In a clusterer or outlier detector the prediction is an integer

If the estimator was not already fitted calling this method should raise a `exceptions.NotFittedError`

Output conventions

classifier An array of shape `n_samples` `n_outputs` Multilabel data may be represented as a sparse matrix if a sparse matrix was used in fitting Each element should be one of the values in the classifier’s `classes` attribute

clusterer An array of shape `n_samples` where each value is from 0 to `n_clusters - 1` if the corresponding sample is clustered and `-1` if the sample is not clustered as in `clusterdbSCAN`

outlier detector An array of shape `n_samples` where each value is `1` for an outlier and `0` otherwise

scikitlearn user guide Release 0213

regressor A numeric array of shape nsamples usually float64 Some regressors have extra options in their predict method allowing them to return standard deviation returnstdTrue or covariance returncovTrue relative to the predicted value In this case the return value is a tuple of arrays corresponding to prediction mean std cov as required
predictlogproba The natural logarithm of the output of predictproba provided to facilitate numerical stability

predictproba A method in classifiers and clusterers that are able to return probability estimates for each class cluster Its input is usually only some observed data X

If the estimator was not already fitted calling this method should raise a exceptionsNotFittedError
Output conventions are like those for decisionfunction except in the binary classification case where one column is output for each class while decisionfunction outputs a 1d array For binary and multiclass predictions each row should add to 1

Like other methods predictproba should only be present when the estimator can make probabilistic predictions see duck typing This means that the presence of the method may depend on estimator parameters eg inlinearmodelSGDClassifier or training data eg in modelselectionGridSearchCV and may only appear after fitting

score A method on an estimator usually a predictor which evaluates its predictions on a given dataset and returns a single numerical score A greater return value should indicate better predictions accuracy is used for classifiers and R2 for regressors by default

If the estimator was not already fitted calling this method should raise a exceptionsNotFittedError
Some estimators implement a custom estimatorspecific score function often the likelihood of the data under the model

scoresamples TODO

If the estimator was not already fitted calling this method should raise a exceptionsNotFittedError
setparams Available in any estimator takes keyword arguments corresponding to keys in getparams Each is provided a new value to assign such that calling getparams after setparams will reflect the changed parameters Most estimators use the implementation in baseBaseEstimator which handles nested parameters and otherwise sets the parameter as an attribute on the estimator The method is overridden in pipeline Pipeline and related estimators

split On a CV (Cross-Validation) splitter not an estimator this method accepts parameters Xygroups where all may be optional and returns an iterator over trainidx testidx pairs Each of traintestidx is a 1d integer array with values from 0 from Xshape0 1 of any length such that no values appear in both some trainidx and its corresponding testidx

transform In a transformer transforms the input usually only X into some transformed space conventionally notated as Xt Output is an array or sparse matrix of length nsamples and with number of columns fixed after fitting

If the estimator was not already fitted calling this method should raise a exceptionsNotFittedError

45 Parameters

These common parameter names specifically used in estimator construction see concept parameter sometimes also appear as parameters of functions or nonestimator constructors

classweight Used to specify sample weights when fitting classifiers as a function of the target class Where sampleweight is also supported and given it is multiplied by the classweight contribution Similarly

678 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

whereclassweight is used in a multioutput including multilabel tasks the weights are multiplied across outputs ie columns of y

By default all samples have equal weight such that classes are effectively weighted by their their prevalence in the training data This could be achieved explicitly with classweightlabel1 1 label2 1 for all class labels

More generally classweight is specified as a dict mapping class labels to weights classlabel weight such that each sample of the named class is given that weight classweightbalanced can be used to give all classes equal weight by giving each sample a weight inversely related to its class's prevalence in the training data nsamples nclasses np bincounty Class weights will be used differently depending on the algorithm for linear models such as linear SVM (Support Vector Machine) or logistic regression the class weights will alter the loss function by weighting the loss of each sample by its class weight For treebased algorithms the class weights will be used for reweighting the splitting criterion Note however that this rebalancing does not take the weight of samples in each class into account For multioutput classification a list of dicts is used to specify weights for each output For example for four class multilabel classification weights should be 0 1 1 1 0 1 1 5 0 1 1 1 0 1 1 1 instead of 11 25 31 41

Theclassweight parameter is validated and interpreted with utilscomputeclasseweight cv Determines a cross validation splitting strategy as used in crossvalidation based routines cv is also available in estimators such as multioutputClassifierChain orcalibration CalibratedClassifierCV which use the predictions of one estimator as training data for another to not overfit the training supervision

Possible inputs for cvare usually

- An integer specifying the number of folds in Kfold cross validation Kfold will be stratified over classes if the estimator is a classifier determined by baseisclassifier and the targets may represent a binary or multiclass but not multioutput classification problem determined by utilsmulticlass typeoftarget

- Acrossvalidation splitter instance Refer to the User Guide for splitters available within Scikitlearn
- An iterable yielding traintest splits

With some exceptions especially where not using cross validation at all is an option the default is 3fold and will change to 5fold in version 022

cvvalues are validated and interpreted with utilscheckcv

kernel TODO

maxiter For estimators involving iterative optimization this determines the maximum number of iterations to be performed in fit Ifmaxiter iterations are run without convergence a exceptions ConvergenceWarning should be raised Note that the interpretation of "a single iteration" is inconsistent across estimators some but not all use it to mean a single epoch ie a pass over every sample in the data FIXME perhaps we should have some common tests about the relationship between ConvergenceWarning and maxiter

memory Some estimators make use of joblibMemory to store partial solutions during fitting Thus when fit is called again those partial solutions have been memoized and can be reused Amemory parameter can be specified as a string with a path to a directory or a joblibMemory instance or an object with a similar interface ie a cache method can be used memory values are validated and interpreted with utilsvalidationcheckmemory

45 Parameters 679

scikitlearn user guide Release 0213

metric As a parameter this is the scheme for determining the distance between two data points See metrics pairwise distances In practice for some algorithms an improper distance metric one that does not obey the triangle inequality such as Cosine Distance may be used

XXX hierarchical clustering uses affinity with this meaning

We also use metric to refer to evaluation metrics but avoid using this sense as a parameter name

ncomponents The number of features which a transformer should transform the input into See components for the special case of affine projection

niternochange Number of iterations with no improvement to wait before stopping the iterative procedure

This is also known as a patience parameter It is typically used with early stopping to avoid stopping too early

njobs This is used to specify how many concurrent processes threads should be used for parallelized routines

Scikitlearn uses one processor for its processing by default although it also makes use of NumPy which may be configured to use a threaded numerical processor library like MKL see FAQ

njobs is an int specifying the maximum number of concurrently running jobs If set to 1 all CPUs are used

If 1 is given no joblib level parallelism is used at all which is useful for debugging Even with njobs

1 parallelism may occur due to numerical processing libraries see FAQ For njobs below 1 ncpus 1

njobs are used Thus for njobs 2 all CPUs but one are used

njobsNone means unset it will generally be interpreted as njobs1 unless the current joblib

Parallel backend context specifies otherwise

The use of njobs based parallelism in estimators varies

- Most often parallelism happens in fitting but sometimes parallelism happens in prediction eg in random forests

- Some parallelism uses a multithreading backend by default some a multiprocessing backend It is possible to override the default backend by using sklearnutilsparallelbackend

- Whether parallel processing is helpful at improving runtime depends on many factors and it's usually a good idea to experiment rather than assuming that increasing the number of jobs is always a good thing It can be highly detrimental to performance to run multiple copies of some estimators or functions in parallel

Nested uses of njobs based parallelism with the same backend will result in an exception So

GridSearchCVOneVsRestClassifierSVC njobs2 njobs2 won't work

When njobs is not 1 the estimator being parallelized must be picklable This means for instance that

lambdas cannot be used as estimator parameters

randomstate Whenever randomization is part of a Scikitlearn algorithm a randomstate parameter may be provided to control the random number generator used Note that the mere presence of randomstate doesn't mean that randomization is always used as it may be dependent on another parameter eg shuffle being set

randomstate 's value may be

None default Use the global random state from numpyrandom

An integer Use a new random number generator seeded by the given integer To make a randomized algorithm deterministic ie running it multiple times will produce the same result an arbitrary integer

randomstate can be used However it may be worthwhile checking that your results are stable across a number of different distinct random seeds Popular integer random seeds are 0 and 42

AnumpyrandomRandomState instance Use the provided random state only affecting other users of the same random state instance Calling fit multiple times will reuse the same instance and will produce different results

680 Chapter 4 Glossary of Common Terms and API (Application Programming Interface) Elements

scikitlearn user guide Release 0213

utilscheckrandomstate is used internally to validate the input randomstate and return a RandomState instance

scoring Specifies the score function to be maximized usually by cross validation or – in some cases – multiple score functions to be reported The score function can be a string accepted by metricsgetscorer or a callable scorer not to be confused with an evaluation metric as the latter have a more diverse API (Application Programming Interface) scoring may also be set to None in which case the estimator’s score method is used See The scoring parameter defining model evaluation rules in the User Guide

Where multiple metrics can be evaluated scoring may be given either as a list of unique strings or a dict with names as keys and callables as values Note that this does not specify which score function is to be maximised and another parameter such as refit may be used for this purpose

The scoring parameter is validated and interpreted using metricscheckscoring

verbose Logging is not handled very consistently in Scikitlearn at present but when it is provided as an option the verbose parameter is usually available to choose no logging set to False Any True value should enable some logging but larger integers eg above 10 may be needed for full verbosity Verbose logs are usually printed to Standard Output Estimators should not produce any output on Standard Output with the default verbose setting

warmstart When fitting an estimator repeatedly on the same dataset but for multiple parameter values such as to find the value maximizing performance as in grid search it may be possible to reuse aspects of the model learnt from the previous parameter value saving time When warmstart is true the existing fitted model attributes are used to initialise the new model in a subsequent call to fit

Note that this is only applicable for some models and some parameters and even some orders of parameter values For example warmstart may be used when building random forests to add more trees to the forest increasing nestimators but not to reduce their number

partialfit also retains the model between calls but differs with warmstart the parameters change and the data is more or less constant across calls to fit with partialfit the minibatch of data changes and model parameters stay fixed

There are cases where you want to use warmstart to fit on different but closely related data For example one may initially fit to a subset of the data then finetune the parameter search on the full dataset For classification all data in a sequence of warmstart calls to fit must include samples from each class

46 Attributes

See concept attribute

classes A list of class labels known to the classifier mapping each label to a numerical index used in the model representation our output For instance the array output from predictproba has columns aligned with classes For multioutput classifiers classes should be a list of lists with one class listing for each output For each output the classes should be sorted numerically or lexicographically for strings classes and the mapping to indices is often managed with preprocessingLabelEncoder

components An affine transformation matrix of shape ncomponents nfeatures used in many linear transformers where ncomponents is the number of output features and nfeatures is the number of input features

See also components which is a similar attribute for linear predictors

coef The weightcoefficient matrix of a generalised linear model predictor of shapenfeatures for binary classification and singleoutput regression nclasses nfeatures for multiclass classification and ntargets nfeatures for multioutput regression Note this does not include the intercept or bias term which is stored in intercept

46 Attributes 681

scikitlearn user guide Release 0213

When available featureimportances is not usually provided as well but can be calculated as the norm of each feature's entry in coef

See also components which is a similar attribute for linear transformers

embedding An embedding of the training data in manifold learning estimators with shape nsamples

ncomponents identical to the output of fittransform See also labels

niter The number of iterations actually performed when fitting an iterative estimator that may stop upon convergence See also maxiter

featureimportances A vector of shape nfeatures available in some predictors to provide a relative measure of the importance of each feature in the predictions of the model

labels A vector containing a cluster label for each sample of the training data in clusterers identical to the output

offitpredict See also embedding

47 Data and sample properties

See concept sample property

groups Used in cross validation routines to identify samples which are correlated Each value is an identifier such that in a supporting CV (Cross-Validation) splitter samples from some groups value may not appear in both a training set and its corresponding test set See Crossvalidation iterators for grouped data

sampleweight A relative weight for each sample Intuitively if all weights are integers a weighted model or score should be equivalent to that calculated when repeating the sample the number of times specified in the weight Weights may be specified as floats so that sample weights are usually equivalent up to a constant positive scaling factor

FIXME Is this interpretation always the case in practice We have no common tests

Some estimators such as decision trees support negative weights FIXME This feature or its absence may not be tested or documented in many estimators

This is not entirely the case where other parameters of the model consider the number of samples in a region as withminsamples inclusterDBSCAN In this case a count of samples becomes to a sum of their weights

In classification sample weights can also be specified as a function of class with the classweight estimator parameter

XDenotes data that is observed at training and prediction time used as independent variables in learning The notation is uppercase to denote that it is ordinarily a matrix see rectangular When a matrix each sample may be represented by a feature vector or a vector of precomputed dissimilarity with each training sample Xmay also not be a matrix and may require a feature extractor or apairwise metric to turn it into one before learning a model

Xt Shorthand for "transformed X"

y

YDenotes data that may be observed at training time as the dependent variable in learning but which is unavailable at prediction time and is usually the target of prediction The notation may be uppercase to denote that it is a matrix representing multioutput targets for instance but usually we use yand sometimes do so even when multiple outputs are assumed

512 Isotonic Regression
An illustration of the isotonic regression on generated data The isotonic regression finds a nondecreasing approximation of a function while minimizing the mean squared error on the training data The benefit of such a model is that it does not assume any form for the target function such as linearity For comparison a linear regression is also presented

513 Face completion with a multi-output estimator

This example shows the use of a multi-output estimator to complete images. The goal is to predict the lower half of a face given its upper half.

The first column of images shows true faces. The next columns illustrate how extremely randomized trees, k-nearest neighbors, linear regression, and ridge regression complete the lower half of those faces.

514 Multilabel classification

This example simulates a multilabel document classification problem The dataset is generated randomly based on the following process

- pick the number of labels n Poissonnlabels
- n times choose a class c c Multinomialtheta
- pick the document length k Poissonlength
- k times choose a word w Multinomialthetac

In the above process rejection sampling is used to make sure that n is more than 2 and that the document length is never zero Likewise we reject classes which have already been chosen The documents that are assigned to both classes are plotted surrounded by two colored circles

The classification is performed by projecting to the first two principal components found by PCA (Principal Component Analysis) and CCA for visualisation purposes followed by using the sklearnmulticlassOneVsRestClassifier metaclassifier using two SVCs with linear kernels to learn a discriminative model for each class Note that PCA (Principal Component Analysis) is used to perform an unsupervised dimensionality reduction while CCA is used to perform a supervised one Note in the plot “unlabeled samples” does not mean that we don’t know the labels as in semisupervised learning but that the samples simply do nothave a label

515 Comparing anomaly detection algorithms for outlier detection on toy datasets

This example shows characteristics of different anomaly detection algorithms on 2D datasets. Datasets contain one or two modes/regions of high density to illustrate the ability of algorithms to cope with multimodal data.

For each dataset, 15% of samples are generated as random uniform noise. This proportion is the value given to the `nu` parameter of the `OneClassSVM` and the contamination parameter of the other outlier detection algorithms. Decision boundaries between inliers and outliers are displayed in black except for Local Outlier Factor (LOF) as it has no predict method to be applied on new data when it is used for outlier detection.

`sklearnsvmOneClassSVM` is known to be sensitive to outliers and thus does not perform very well for outlier detection. This estimator is best suited for novelty detection when the training set is not contaminated by outliers. That said, outlier detection in high dimension or without any assumptions on the distribution of the inlying data is very challenging and a `OneClass SVM` (Support Vector Machine) might give useful results in these situations depending on the value of its hyperparameters.

`sklearn covariance EllipticEnvelope` assumes the data is Gaussian and learns an ellipse. It thus degrades when the data is not unimodal. Notice however that this estimator is robust to outliers.

`sklearn ensemble IsolationForest` and `sklearn neighbors LocalOutlierFactor` seem

to perform reasonably well for multimodal data sets. The advantage of `sklearn neighbors`

`LocalOutlierFactor` over the other estimators is shown for the third data set where the two modes have different densities. This advantage is explained by the local aspect of LOF meaning that it only compares the score of abnormality of one sample with the scores of its neighbors.

Finally, for the last data set, it is hard to say that one sample is more abnormal than another sample as they are uniformly distributed in a hypercube. Except for the `sklearnsvmOneClassSVM` which overfits a little, all estimators present decent solutions for this situation. In such a case, it would be wise to look more closely at the scores of abnormality of the samples as a good estimator should assign similar scores to all the samples.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

Finally, note that parameters of the models have been here handpicked but that in practice they need to be adjusted. In the absence of labelled data, the problem is completely unsupervised so model selection can be a challenge.

5.16 The Johnson-Lindenstrauss bound for embedding with random projections

The Johnson-Lindenstrauss lemma states that any high dimensional dataset can be randomly projected into a lower dimensional Euclidean space while controlling the distortion in the pairwise distances.

Theoretical bounds

The distortion introduced by a random projection is asserted by the fact that is defining an embedding with good probability as defined by

$$1 - \frac{1}{n} \sum_{i=1}^n \left| \frac{\|u_i - v_i\|^2}{\|u_i - v_i\|^2} - \frac{\|u_i - v_i\|^2}{\|u_i - v_i\|^2} \right| \leq \frac{1}{n} \sum_{i=1}^n \left| \frac{\|u_i - v_i\|^2}{\|u_i - v_i\|^2} - \frac{\|u_i - v_i\|^2}{\|u_i - v_i\|^2} \right|$$

Where u and v are any rows taken from a dataset of shape $n \times m$ and p is a projection by a random Gaussian $N(0, 1)$ matrix with shape $n \times m$ or a sparse Achlioptas matrix.

The minimum number of components to guarantees the embedding is given by

$$m \geq \frac{4 \log(n) \log(1/\epsilon)}{\epsilon^2}$$

694 Chapter 5 Examples

scikitlearn user guide Release 0213

The first plot shows that with an increasing number of samples `nsamples` the minimal number of dimensions `ncomponents` increased logarithmically in order to guarantee an `epembedding`

The second plot shows that an increase of the admissible distortion `eps` allows to reduce drastically the minimal number of dimensions `ncomponents` for a given number of samples `nsamples`

Empirical validation

We validate the above bounds on the digits dataset or on the 20 newsgroups text document TFIDF word frequencies dataset

- for the digits dataset some 8x8 gray level pixels data for 500 handwritten digits pictures are randomly projected to spaces for various larger number of dimensions `ncomponents`
- for the 20 newsgroups dataset some 500 documents with 100k features in total are projected using a sparse random matrix to smaller euclidean spaces with various values for the target number of dimensions `ncomponents`

The default dataset is the digits dataset To run the example on the twenty newsgroups dataset pass the `-twentynewsgroups` command line argument to this script

For each value of `ncomponents` we plot

- 2D distribution of sample pairs with pairwise distances in original and projected spaces as x and y axis respectively
- 1D histogram of the ratio of those distances projected / original

We can see that for low values of `ncomponents` the distribution is wide with many distorted pairs and a skewed distribution due to the hard limit of zero ratio on the left as distances are always positives while for larger values of `ncomponents` the distortion is controlled and the distances are well preserved by the random projection

Remarks

According to the JL lemma projecting 500 samples without too much distortion will require at least several thousands dimensions irrespective of the number of features of the original dataset

Hence using random projections on the digits dataset which only has 64 features in the input space does not make sense it does not allow for dimensionality reduction in this case

On the twenty newsgroups on the other hand the dimensionality can be decreased from 56436 down to 10000 while reasonably preserving pairwise distances

517 Comparison of kernel ridge regression and SVR (Support Vector Regression)

Both kernel ridge regression KRR and SVR (Support Vector Regression) learn a nonlinear function by employing the kernel trick ie they learn a linear function in the space induced by the respective kernel which corresponds to a nonlinear function in the original space They differ in the loss functions ridge versus epsiloninsensitive loss In contrast to SVR (Support Vector Regression) fitting a KRR can be done in closedform and is typically faster for mediumsized datasets On the other hand the learned model is nonsparse and thus slower than SVR (Support Vector Regression) at predictiontime This example illustrates both methods on an artificial dataset which consists of a sinusoidal target function and strong noise added to every fifth datapoint The first figure compares the learned model of KRR and SVR (Support Vector Regression) when both complexityregularization and bandwidth of the RBF (Radial Basis Function) kernel are optimized using gridsearch The learned functions are very similar however fitting KRR is approx seven times faster than fitting SVR (Support Vector Regression) both with gridsearch However prediction of 100000 target values is more than tree times faster with SVR (Support Vector Regression) since it has learned a sparse model using only approx 13 of the 100 training datapoints as support vectors The next figure compares the time for fitting and prediction of KRR and SVR (Support Vector Regression) for different sizes of the training set Fitting KRR is faster than SVR (Support Vector Regression) for medium sized training sets less than 1000 samples however for larger training sets SVR (Support Vector Regression) scales better With regard to prediction time SVR (Support Vector Regression) is faster than KRR for all sizes of the learned sparse solution Note that the degree of sparsity and thus the prediction time depends on the parameters epsilon and C of the SVR (Support Vector Regression)

518 Explicit feature map approximation for RBF (Radial Basis Function) kernels

An example illustrating the approximation of the feature map of an RBF (Radial Basis Function) kernel

It shows how to use RBFSampler andNystroem to approximate the feature map of an RBF (Radial Basis Function) kernel for classification

with an SVM (Support Vector Machine) on the digits dataset Results using a linear SVM (Support Vector Machine) in the original space a linear SVM

imate mappings and using a kernelized SVM (Support Vector Machine) are compared Timings and accuracy for varying amounts of Monte

Carlo samplings in the case of RBFSampler which uses random Fourier features and different sized subsets of the

training set for Nystroem for the approximate mapping are shown

Please note that the dataset here is not large enough to show the benefits of kernel approximation as the exact SVM (Support Vector Machine) is

still reasonably fast

Sampling more dimensions clearly leads to better classification results but comes at a greater cost This means there

is a tradeoff between runtime and accuracy given by the parameter ncomponents Note that solving the Linear

SVM (Support Vector Machine) and also the approximate kernel SVM (Support Vector Machine) could be greatly accelerated by using stochastic gra

sklearnlinearmodelSGDClassifier This is not easily possible for the case of the kernelized SVM (Support Vector Machine)

The second plot visualized the decision surfaces of the RBF (Radial Basis Function) kernel SVM (Support Vector Machine) and the linear SVM (Supp

maps The plot shows decision surfaces of the classifiers projected onto the first two principal components of the data

This visualization should be taken with a grain of salt since it is just an interesting slice through the decision surface

in 64 dimensions In particular note that a datapoint represented as a dot does not necessarily be classified into the

region it is lying in since it will not lie on the plane that the first two principal components span

The usage of RBFSampler andNystroem is described in detail in Kernel Approximation

521 Outlier detection on a real data set

This example illustrates the need for robust covariance estimation on a real data set It is useful both for outlier detection and for a better understanding of the data structure

We selected two sets of two variables from the Boston housing data set as an illustration of what kind of analysis can be done with several outlier detection tools For the purpose of visualization we are working with twodimensional examples but one should be aware that things are not so trivial in highdimension as it will be pointed out

In both examples below the main result is that the empirical covariance estimate as a nonrobust one is highly influenced by the heterogeneous structure of the observations Although the robust covariance estimate is able to focus on the main mode of the data distribution it sticks to the assumption that the data should be Gaussian distributed yielding some biased estimation of the data structure but yet accurate to some extent The OneClass SVM (Support Vector Machine) does not assume any parametric form of the data distribution and can therefore model the complex shape of the data much better

First example

The first example illustrates how robust covariance estimation can help concentrating on a relevant cluster when another one exists Here many observations are confounded into one and break down the empirical covariance estimation Of course some screening tools would have pointed out the presence of two clusters Support Vector Machines Gaussian Mixture Models univariate outlier detection But had it been a highdimensional example none of these could be applied that easily

Second example

The second example shows the ability of the Minimum Covariance Determinant robust estimator of covariance to concentrate on the main mode of the data distribution the location seems to be well estimated although the covariance is hard to estimate due to the bananashaped distribution Anyway we can get rid of some outlying observations The OneClass SVM (Support Vector Machine) is able to capture the real data structure but the difficulty is to adjust its kernel bandwidth parameter so as to obtain a good compromise between the shape of the data scatter matrix and the risk of overfitting the data

522 Compressive sensing tomography reconstruction with L1 prior Lasso

This example shows the reconstruction of an image from a set of parallel projections acquired along different angles

Such a dataset is acquired in computed tomography CT

Without any prior information on the sample the number of projections required to reconstruct the image is of the

order of the linear size of the image in pixels For simplicity we consider here a sparse image where only pixels

on the boundary of objects have a nonzero value Such data could correspond for example to a cellular material

Note however that most images are sparse in a different basis such as the Haar wavelets Only 17 projections are

acquired therefore it is necessary to use prior information available on the sample its sparsity this is an example of

compressive sensing

The tomography projection operation is a linear transformation In addition to the datafidelity term corresponding

to a linear regression we penalize the L1 norm of the image to account for its sparsity The resulting optimization

problem is called the Lasso We use the class `sklearnlinearmodelLasso` that uses the coordinate descent

algorithm Importantly this implementation is more computationally efficient on a sparse matrix than the projection

operator used here

The reconstruction with L1 penalization gives a result with zero error all pixels are successfully labeled with 0 or 1

even if noise was added to the projections In comparison an L2 penalization `sklearnlinearmodelRidge`

produces a large number of labeling errors for the pixels Important artifacts are observed on the reconstructed image

contrary to the L1 penalization Note in particular the circular artifact separating the pixels in the corners that have

contributed to fewer projections than the central disk

523 Topic extraction with Nonnegative Matrix Factorization and Latent Dirichlet Allocation

This is an example of applying sklearndecompositionNMF andsklearndecompositionLatentDirichletAllocation on a corpus of documents and extract additive models of the topic structure

722 Chapter 5 Examples

scikitlearn user guide Release 0213

of the corpus The output is a list of topics each represented as a list of terms weights are not shown

Nonnegative Matrix Factorization is applied with two different objective functions the Frobenius norm and the generalized KullbackLeibler divergence The latter is equivalent to Probabilistic Latent Semantic Indexing

The default parameters nsamples nfeatures ncomponents should make the example runnable in a couple of tens of seconds You can try to increase the dimensions of the problem but be aware that the time complexity is polynomial in NMF (Non-Negative Matrix Factorization) In LDA the time complexity is proportional to nsamples iterations

526 Species distribution modeling

Modeling species’ geographic distributions is an important problem in conservation biology In this example we model the geographic distribution of two south american mammals given past observations and 14 environmental variables Since we have only positive examples there are no unsuccessful observations we cast this problem as a density estimation problem and use the OneClassSVM provided by the package sklearnsvm as our modeling tool The dataset is provided by Phillips et al 2006 If available the example uses basemap to plot the coast lines and national boundaries of South America

The two species are

- “Bradypus variegatus” the Browthroated Sloth
- “Microryzomys minutus” also known as the Forest Small Rice Rat a rodent that lives in Peru Colombia Ecuador Peru and Venezuela

527 Visualizing the stock market structure

This example employs several unsupervised learning techniques to extract the stock market structure from variations in historical quotes

The quantity that we use is the daily variation in quote price quotes that are linked tend to cofluctuate during a day

Learning a graph structure

We use sparse inverse covariance estimation to find which quotes are correlated conditionally on the others Specifi cally sparse inverse covariance gives us a graph that is a list of connection For each symbol the symbols that it is connected too are those useful to explain its fluctuations

Clustering

We use clustering to group together quotes that behave similarly Here amongst the various clustering techniques available in the scikitlearn we use Affinity Propagation as it does not enforce equalsize clusters and it can choose automatically the number of clusters from the data

Note that this gives us a different indication than the graph as the graph reflects conditional relations between variables while the clustering reflects marginal properties variables clustered together can be considered as having a similar impact at the level of the full stock market

Embedding in 2D space

For visualization purposes we need to lay out the different symbols on a 2D canvas For this we use Manifold learning techniques to retrieve 2D embedding

52 Examples based on real world datasets 741

scikitlearn user guide Release 0213

Visualization

The output of the 3 models are combined in a 2D graph where nodes represents the stocks and edges the

- cluster labels are used to define the color of the nodes
- the sparse covariance model is used to display the strength of the edges
- the 2D embedding is used to position the nodes in the plan

This example has a fair amount of visualizationrelated code as visualization is crucial here to display the graph One of the challenge is to position the labels minimizing overlap For this we use an heuristic based on the direction of the nearest neighbor along each axis

528 Wikipedia principal eigenvector
A classical way to assert the relative importance of vertices in a graph is to compute the principal eigenvector of the adjacency matrix so as to assign to each vertex the values of the components of the first eigenvector as a centrality score
https://en.wikipedia.org/wiki/Eigenvector_centrality
On the graph of webpages and links those values are called the PageRank scores by Google
The goal of this example is to analyze the graph of links inside wikipedia articles to rank articles by relative importance according to this eigenvector centrality
The traditional way to compute the principal eigenvector is to use the power iteration method
https://en.wikipedia.org/wiki/Power_iteration
746 Chapter 5 Examples

scikitlearn user guide Release 0213

Here the computation is achieved thanks to Martinsson’s Randomized SVD algorithm implemented in scikitlearn
The graph data is fetched from the DBpedia dumps DBpedia is an extraction of the latent structured data of the Wikipedia content

5210 Prediction Latency

This is an example showing the prediction latency of various scikitlearn estimators

The goal is to measure the latency one can expect when doing predictions either in bulk or atomic ie one by one

mode

The plots represent the distribution of the prediction latency as a boxplot

5211 Outofcore classification of text documents
This is an example showing how scikitlearn can be used for classification using an outofcore approach learning
from data that doesn't fit into main memory We make use of an online classifier ie one that supports the partialfit
method that will be fed with batches of examples To guarantee that the features space remains the same over time
52 Examples based on real world datasets 763

scikitlearn user guide Release 0213

we leverage a HashingVectorizer that will project each example into the same feature space This is especially useful in the case of text classification where new features words may appear in each batch

The dataset used in this example is Reuters21578 as provided by the UCI ML repository It will be automatically downloaded and uncompressed on first run

The plot represents the learning curve of the classifier the evolution of classification accuracy over the course of the minibatches Accuracy is measured on the first 1000 samples held out as a validation set

To limit the memory consumption we queue examples up to a fixed amount before feeding them to the learner

533 Biclustering documents with the Spectral Coclustering algorithm
This example demonstrates the Spectral Coclustering algorithm on the twenty newsgroups dataset The 'composms
windowmisc' category is excluded because it contains many posts containing nothing but data
The TFIDF vectorized posts form a word frequency matrix which is then biclustered using Dhillon's Spectral Co
Clustering algorithm The resulting documentword biclusters indicate subsets words used more often in those subsets
documents
For a few of the best biclusters its most common document categories and its ten most important words get printed
The best biclusters are determined by their normalized cut The best words are determined by comparing their sums
inside and outside the bicluster
For comparison the documents are also clustered using MiniBatchKMeans The document clusters derived from the
biclusters achieve a better Vmeasure than clusters found by MiniBatchKMeans

541 Comparison of Calibration of Classifiers

Well calibrated classifiers are probabilistic classifiers for which the output of the predict_proba method can be directly interpreted as a confidence level. For instance, a well calibrated binary classifier should classify the samples such that among the samples to which it gave a predict_proba value close to 0.8, approx. 80% actually belong to the positive class.

LogisticRegression returns well calibrated predictions as it directly optimizes logloss. In contrast, the other methods return biased probabilities with different biases per method.

- GaussianNaiveBayes tends to push probabilities to 0 or 1; note the counts in the histograms. This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.
- RandomForestClassifier shows the opposite behavior: the histograms show peaks at approx. 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana: "Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0, 1], errors caused by variance tend to be one-sided: near zero and one. For example, if a model should predict p = 0 for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees, that bagging is averaging over this noise will cause some trees to predict values larger than 0; for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting." As a result, the calibration curve shows a characteristic sigmoid shape, indicating that the classifier could trust its "intuition" more and return probabilities closer to 0 or 1 typically.
- Support Vector Classification (SVC) (Support Vector Classification) shows an even more sigmoid curve than the RandomForestClassifier, which is typical for maximum-margin methods. Compare Niculescu-Mizil and Caruana, which focus on hard samples that are close to the decision boundary, the support vectors.

542 Probability Calibration curves

When performing classification one often wants to predict not only the class label but also the associated probability This probability gives some kind of confidence on the prediction This example demonstrates how to display how well calibrated the predicted probabilities are and how to calibrate an uncalibrated classifier

The experiment is performed on an artificial dataset for binary classification with 100000 samples 1000 of them are used for model fitting with 20 features Of the 20 features only 2 are informative and 10 are redundant The first figure shows the estimated probabilities obtained with logistic regression Gaussian naive Bayes and Gaussian naive Bayes with both isotonic calibration and sigmoid calibration The calibration performance is evaluated with Brier score reported in the legend the smaller the better One can observe here that logistic regression is well calibrated while raw Gaussian naive Bayes performs very badly This is because of the redundant features which violate the assumption of feature independence and result in an overly confident classifier which is indicated by the typical transposed sigmoid curve

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve Sigmoid calibration also improves the brier score slightly albeit not as strongly as the nonparametric isotonic regression This can be attributed to the fact that we have plenty of calibration data such that the greater flexibility of the nonparametric model can be exploited

The second figure shows the calibration curve of a linear support vector classifier LinearSVC LinearSVC shows the opposite behavior as Gaussian naive Bayes the calibration curve has a sigmoid curve which is typical for an underconfident classifier In the case of LinearSVC this is caused by the margin property of the hinge loss which lets the model focus on hard samples that are close to the decision boundary the support vectors Both kinds of calibration can fix this issue and yield nearly identical results This shows that sigmoid calibration can deal with situations where the calibration curve of the base classifier is sigmoid eg for LinearSVC but not where it is transposed sigmoid eg Gaussian naive Bayes

543 Probability calibration of classifiers

When performing classification you often want to predict not only the class label but also the associated probability

This probability gives you some kind of confidence on the prediction However not all classifiers provide well

calibrated probabilities some being overconfident while others being underconfident Thus a separate calibration

of predicted probabilities is often desirable as a postprocessing This example illustrates two different methods for

this calibration and evaluates the quality of the returned probabilities using Brier's score see https://en.wikipedia.org/wiki/Brier_score

wikiBrierscore

Compared are the estimated probability using a Gaussian naive Bayes classifier without calibration with a sigmoid

calibration and with a nonparametric isotonic calibration One can observe that only the nonparametric model is

able to provide a probability calibration that returns probabilities close to the expected 0.5 for most of the samples

belonging to the middle cluster with heterogeneous labels This results in a significantly improved Brier score

544 Probability Calibration for 3class classification

This example illustrates how sigmoid calibration changes predicted probabilities for a 3class classification problem

Illustrated is the standard 2simplex where the three corners correspond to the three classes Arrows point from the

probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier

after sigmoid calibration on a holdout validation set Colors indicate the true class of an instance red class 1 green

class 2 blue class 3

The base classifier is a random forest classifier with 25 base estimators trees If this classifier is trained on all 800

training datapoints it is overly confident in its predictions and thus incurs a large logloss Calibrating an identical

classifier which was trained on 600 datapoints with method'sigmoid' on the remaining 200 datapoints reduces the

confidence of the predictions ie moves the probability vectors from the edges of the simplex towards the center

This calibration results in a lower logloss Note that an alternative would have been to increase the number of base

estimators which would have resulted in a similar decrease in logloss

The digits dataset

digits datasetsloaddigits

The data that we are interested in is made of 8x8 images of digits lets
have a look at the first 4 images stored in the images attribute of the
dataset If we were working from image files we could load them using
matplotlib.pyplot.imread Note that each image must have the same size For these
images we know which digit they represent it is given in the target of
the dataset

553 Plot classification probability

Plot the classification probability for different classifiers We use a 3 class dataset and we classify it with a Support Vector classifier L1 and L2 penalized logistic regression with either a OneVsRest or multinomial setting and Gaussian process classification

Linear SVC (Support Vector Classification) is not a probabilistic classifier by default but it has a builtin calibration option enabled in this example `probability=True`

The logistic regression with OneVsRest is not a multiclass classifier out of the box As a result it has more trouble in separating class 2 and 3 than the other estimators

810 Chapter 5 Examples

554 Classifier comparison
A comparison of a several classifiers in scikitlearn on synthetic datasets The point of this example is to illustrate
the nature of decision boundaries of different classifiers This should be taken with a grain of salt as the intuition
conveyed by these examples does not necessarily carry over to real datasets
Particularly in highdimensional spaces data can more easily be separated linearly and the simplicity of classifiers
such as naive Bayes and linear SVMs might lead to better generalization than is achieved by other classifiers
The plots show training points in solid colors and testing points semitransparent The lower right shows the classifi
cation accuracy on the test set

563 Demonstration of kmeans assumptions

This example is meant to illustrate situations where kmeans will produce unintuitive and possibly unexpected clusters
In the first three plots the input data does not conform to some implicit assumption that kmeans makes and undesirable clusters are produced as a result In the last plot kmeans returns intuitive clusters despite unevenly sized blobs

564 Online learning of a dictionary of parts of faces
This example uses a large dataset of faces to learn a set of 20 x 20 images patches that constitute faces
From the programming standpoint it is interesting because it shows how to use the online API (Application Programming Interface) of the scikitlearn
to process a very large dataset by chunks The way we proceed is that we load an image at a time and extract
randomly 50 patches from this image Once we have accumulated 500 of these patches using 10 images we run the
partialfit method of the online KMeans object MiniBatchKMeans
The verbose setting on the MiniBatchKMeans enables us to see that some clusters are reassigned during the successive
calls to partialfit This is because the number of patches that they represent has become too low and it is better to
choose a random new cluster

566 Agglomerative clustering with and without structure

This example shows the effect of imposing a connectivity graph to capture local structure in the data The graph is

simply the graph of 20 nearest neighbors

Two consequences of imposing a connectivity can be seen First clustering with a connectivity matrix is much faster

Second when using a connectivity matrix single average and complete linkage are unstable and tend to create a few

clusters that grow very quickly Indeed average and complete linkage fight this percolation behavior by considering all

the distances between two clusters when merging them while single linkage exaggerates the behaviour by considering

830 Chapter 5 Examples

scikitlearn user guide Release 0213

only the shortest distance between clusters The connectivity graph breaks this mechanism for average and complete linkage making them resemble the more brittle single linkage This effect is more pronounced for very sparse graphs try decreasing the number of neighbors in kneighborsgraph and with complete linkage In particular having a very small number of neighbors in the graph imposes a geometry that is close to that of single linkage which is well known to have this percolation instability

568 Segmenting the picture of greek coins in regions

This example uses Spectral clustering on a graph created from voxeltovoxel difference on an image to break this image into multiple partlyhomogeneous regions

This procedure spectral clustering on an image is an efficient approximate solution for finding normalized graph cuts There are two options to assign labels

56 Clustering 835

scikitlearn user guide Release 0213

- with ‘kmeans’ spectral clustering will cluster samples in the embedding space using a kmeans algorithm
- whereas ‘discrete’ will iteratively search for the closest partition space to the embedding space

569 Kmeans Clustering

The plots display firstly what a Kmeans algorithm would yield using three clusters It is then shown what the effect of a bad initialization is on the classification process By setting ninit to only 1 default is 10 the amount of times that the algorithm will be run with different centroid seeds is reduced The next plot displays what using eight clusters would deliver and finally the ground truth

5610 Various Agglomerative Clustering on a 2D embedding of digits

An illustration of various linkage option for agglomerative clustering on a 2D embedding of the digits dataset

The goal of this example is to show intuitively how the metrics behave and not to find good clusters for the digits

This is why the example works on a 2D embedding

What this example shows us is the behavior “rich getting richer” of agglomerative clustering that tends to create uneven cluster sizes This behavior is pronounced for the average linkage strategy that ends up with a couple of singleton clusters while in the case of single linkage we get a single central cluster with all other clusters being drawn from noise points around the fringes

5611 Spectral clustering for image segmentation

In this example an image with connected circles is generated and spectral clustering is used to separate the circles In these settings the Spectral clustering approach solves the problem know as ‘normalized graph cuts’ the image is seen as a graph of connected voxels and the spectral clustering algorithm amounts to choosing graph cuts defining regions while minimizing the ratio of the gradient along the cut and the volume of the region

As the algorithm tries to balance the volume ie balance the region sizes if we take circles with different sizes the segmentation fails

In addition as there is no useful information in the intensity of the image or its gradient we choose to perform the spectral clustering on a graph that is only weakly informed by the gradient This is close to performing a V oronoi partition of the graph

In addition we use the mask of the objects to restrict the graph to the outline of the objects In this example we are interested in separating the objects one from the other and not from the background

5614 Color Quantization using KMeans

Performs a pixelwise Vector Quantization VQ of an image of the summer palace China reducing the number of colors required to show the image from 96615 unique colors to 64 while preserving the overall appearance quality In this example pixels are represented in a 3Dspace and Kmeans is used to find 64 color clusters In the image processing literature the codebook obtained from Kmeans the cluster centers is called the color palette Using a single byte up to 256 colors can be addressed whereas an RGB encoding requires 3 bytes per pixel The GIF file format for example uses such a palette For comparison a quantized image using a random codebook colors picked up randomly is also shown

5615 Hierarchical clustering structured vs unstructured ward

Example builds a swiss roll dataset and runs hierarchical clustering on their position

For more information see Hierarchical clustering

In a first step the hierarchical clustering is performed without connectivity constraints on the structure and is solely based on distance whereas in a second step the clustering is restricted to the kNearest Neighbors graph it's a hierarchical clustering with structure prior

Some of the clusters learned without connectivity constraints do not respect the structure of the swiss roll and extend across different folds of the manifolds On the opposite when opposing connectivity constraints the clusters form a nice parcellation of the swiss roll

5616 Agglomerative clustering with different metrics

Demonstrates the effect of different metrics on the hierarchical clustering

The example is engineered to show the effect of the choice of different metrics It is applied to waveforms which can be seen as highdimensional vector Indeed the difference between metrics is usually more pronounced in high dimension in particular for euclidean and cityblock

We generate data from three groups of waveforms Two of the waveforms waveform 1 and waveform 2 are proportional one to the other The cosine distance is invariant to a scaling of the data as a result it cannot distinguish these two waveforms Thus even with no noise clustering using this distance will not separate out waveform 1 and 2 We add observation noise to these waveforms We generate very sparse noise only 6 of the time points contain noise As a result the l1 norm of this noise ie “cityblock” distance is much smaller than it’s l2 norm “euclidean” distance This can be seen on the interclass distance matrices the values on the diagonal that characterize the spread of the class are much bigger for the Euclidean distance than for the cityblock distance

When we apply clustering to the data we find that the clustering reflects what was in the distance matrices Indeed for the Euclidean distance the classes are illseparated because of the noise and thus the clustering does not separate the waveforms For the cityblock distance the separation is good and the waveform classes are recovered Finally the cosine distance does not separate at all waveform 1 and 2 thus the clustering puts them in the same cluster

5617 Inductive Clustering

Clustering can be expensive especially when our dataset contains millions of datapoints Many clustering algorithms are not inductive and so cannot be directly applied to new data samples without recomputing the clustering which may be intractable Instead we can use clustering to then learn an inductive model with a classifier which has several benefits

- it allows the clusters to scale and apply to new data
- unlike refitting the clusters to new samples it makes sure the labelling procedure is consistent over time
- it allows us to use the inferential capabilities of the classifier to describe or explain the clusters

This example illustrates a generic implementation of a metaestimator which extends clustering by inducing a classifier from the cluster labels

5618 Demo of OPTICS clustering algorithm

Finds core samples of high density and expands clusters from them This example uses data that is generated so

that the clusters have different densities The sklearnclusterOPTICS is first used with its Xi cluster detec

tion method and then setting specific thresholds on the reachability which corresponds to sklearncluster

DBSCAN We can see that the different clusters of OPTICS's Xi method can be recovered with different choices of

thresholds in DBSCAN

5619 Compare BIRCH and MiniBatchKMeans

This example compares the timing of Birch with and without the global clustering step and MiniBatchKMeans on a synthetic dataset having 100000 samples and 2 features generated using makeblobs

Ifnclusters is set to None the data is reduced from 100000 samples to a set of 158 clusters This can be viewed as a preprocessing step before the final global clustering step that further reduces these 158 clusters to 100 clusters

Out
Birch without global clustering as the final step took 247 seconds

nclusters 158

Birch with global clustering as the final step took 290 seconds

nclusters 100

Time taken to run MiniBatchKMeans 360 seconds

5620 Empirical evaluation of the impact of kmeans initialization

Evaluate the ability of kmeans initializations strategies to make the algorithm convergence robust as measured by the relative standard deviation of the inertia of the clustering ie the sum of squared distances to the nearest cluster center

The first plot shows the best inertia reached for each combination of the model KMeans orMiniBatchKMeans and the init method initempty orinitkmeans for increasing values of the ninit parameter that controls the number of initializations

The second plot demonstrate one single run of the MiniBatchKMeans estimator using a initempty and ninit1 This run leads to a bad convergence local optimum with estimated centers stuck between ground truth clusters

The dataset used for evaluation is a 2D grid of isotropic Gaussian clusters widely spaced

5621 Adjustment for chance in clustering performance evaluation

The following plots demonstrate the impact of the number of clusters and number of samples on various clustering performance evaluation metrics

Nonadjusted measures such as the VMeasure show a dependency between the number of clusters and the number of samples: the mean VMeasure of random labeling increases significantly as the number of clusters is closer to the total number of samples used to compute the measure

Adjusted for chance measure such as ARI display some random variations centered around a mean score of 0.0 for any number of samples and clusters

Only adjusted measures can hence safely be used as a consensus index to evaluate the average stability of clustering algorithms for a given value of k on various overlapping subsamples of the dataset

5625 Comparing different hierarchical linkage methods on toy datasets

This example shows characteristics of different linkage methods for hierarchical clustering on datasets that are “inter

esting” but still in 2D

The main observations to make are

- single linkage is fast and can perform well on nonglobular data but it performs poorly in the presence of noise
- average and complete linkage perform well on cleanly separated globular clusters but have mixed results other wise
- Ward is the most effective method for noisy data

While these examples give some intuition about the algorithms this intuition might not apply to very high dimensional data

5626 Selecting the number of clusters with silhouette analysis on KMeans clustering

Silhouette analysis can be used to study the separation distance between the resulting clusters. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters and thus provides a way to assess parameters like number of clusters visually. This measure has a range of 1. 1. Silhouette coefficients as these values are referred to as near 1 indicate that the sample is far away from the neighboring clusters. A value of 0 indicates that the sample is on or very close to the decision boundary between two neighboring clusters and negative values indicate that those samples might have been assigned to the wrong cluster. In this example the silhouette analysis is used to choose an optimal value for nclusters. The silhouette plot shows that thenclusters value of 3, 5 and 6 are a bad pick for the given data due to the presence of clusters with below average silhouette scores and also due to wide fluctuations in the size of the silhouette plots. Silhouette analysis is more ambivalent in deciding between 2 and 4. Also from the thickness of the silhouette plot the cluster size can be visualized. The silhouette plot for cluster 0 when nclusters is equal to 2 is bigger in size owing to the grouping of the 3 sub clusters into one big cluster. However when thenclusters is equal to 4 all the plots are more or less of similar thickness and hence are of similar sizes as can be also verified from the labelled scatter plot on the right.

5627 Comparing different clustering algorithms on toy datasets

This example shows characteristics of different clustering algorithms on datasets that are “interesting” but still in 2D

With the exception of the last dataset the parameters of each of these datasetalgorithm pairs has been tuned to produce good clustering results Some algorithms are more sensitive to parameter values than others

The last dataset is an example of a ‘null’ situation for clustering the data is homogeneous and there is no good clustering For this example the null dataset uses the same parameters as the dataset in the row above it which

represents a mismatch in the parameter values and the data structure

While these examples give some intuition about the algorithms this intuition might not apply to very high dimensional data

57 Pipelines and composite estimators

Examples of how to compose transformers and pipelines from other estimators See the User Guide

Note Click here to download the full example code

908 Chapter 5 Examples

571 Concatenating multiple feature extraction methods

In many realworld examples there are many ways to extract features from a dataset Often it is beneficial to combine several methods to obtain good performance This example shows how to use FeatureUnion to combine features obtained by PCA (Principal Component Analysis) and univariate selection

Combining features using this transformer has the benefit that it allows cross validation and grid searches over the whole process

The combination used in this example is not particularly helpful on this dataset and is only used to illustrate the usage of FeatureUnion

Out

Combined space has 3 features

Fitting 5 folds for each of 18 candidates totalling 90 fits

573 Column Transformer with Mixed Types

This example illustrates how to apply different preprocessing and feature extraction pipelines to different subsets of features using `sklearn.compose.ColumnTransformer`. This is particularly handy for the case of datasets that contain heterogeneous data types since we may want to scale the numeric features and onehot encode the categorical ones.

In this example the numeric data is standard scaled after mean imputation while the categorical data is onehot encoded after imputing missing values with a new category `missing`.

Finally the preprocessing pipeline is integrated in a full prediction pipeline using `sklearn.pipeline`.

Pipeline together with a simple classification model.

Author Pedro Morales partmorales@gmail.com

import pandas as pd

import numpy as np

from sklearn.compose import ColumnTransformer

from sklearn.pipeline import Pipeline

from sklearn.impute import SimpleImputer

from sklearn.preprocessing import StandardScaler, OneHotEncoder

from sklearn.linear_model import LogisticRegression

from sklearn.model_selection import train_test_split, GridSearchCV

np.random.seed(0)

Read data from Titanic dataset

titanic_url = <https://raw.githubusercontent.com/amueller/scipy2017-sklearn/091d371/notebooks/dataset/titanic3.csv>

data = pd.read_csv(titanic_url)

We will train our classifier with the following features:

Numeric Features

age float

fare float

Categorical Features

embarked categories encoded as strings C S Q

sex categories encoded as strings female male

pclass ordinal integers 1 2 3

We create the preprocessing pipelines for both numeric and categorical data

numeric_features = age fare

numeric_transformer = Pipeline(steps=

imputer=SimpleImputer(strategy='median')

scaler=StandardScaler())

categorical_features = embarked sex pclass

categorical_transformer = Pipeline(steps=

imputer=SimpleImputer(strategy='constant', fill_value='missing')

onehot=OneHotEncoder(handle_unknown='ignore')

57 Pipelines and composite estimators 917

```
scikitlearn user guide Release 0213
preprocessor ColumnTransformer
transformers
num numerictransformer numericfeatures
cat categoricaltransformer categoricalfeatures
Append classifier to preprocessing pipeline
Now we have a full prediction pipeline
clf Pipeline(steps=[preprocessor, preprocessor,
classifier LogisticRegression(solver='lbfgs')])
X datadropsurvived axis1
y datasurvived
Xtrain Xtest ytrain ytest train_test_split(X, y, test_size=0.2)
clf.fit(Xtrain, ytrain)
print(model.score(Xtest, ytest))
Out
model score 0.790
Using the prediction pipeline in a grid search
Grid search can also be performed on the different preprocessing steps defined in the
ColumnTransformer object together with the classifier's hyperparameters as part of the Pipeline
We will search for both the imputer strategy of the numeric preprocessing and the regularization parameter
of the logistic regression using sklearn.model_selection.GridSearchCV
param_grid = {
    'preprocessor__num__imputer__strategy': ['mean', 'median'],
    'classifier__C': [0.1, 1.0, 10.0, 100.0]
}
gridsearch = GridSearchCV(clf, param_grid, cv=10, iid=False)
gridsearch.fit(Xtrain, ytrain)
print('best logistic regression from grid search %f' % gridsearch.score(Xtest, ytest))
Out
best logistic regression from grid search 0.798
Total running time of the script: 0 minutes 21.03 seconds
Note: Click here to download the full example code
574 Selecting dimensionality reduction with Pipeline and GridSearchCV
This example constructs a pipeline that does dimensionality reduction followed by prediction with a support vector
classifier. It demonstrates the use of GridSearchCV and Pipeline to optimize over different classes of estimators.
918 Chapter 5 Examples
```

scikitlearn user guide Release 0213

in a single CV (Cross-Validation) run – unsupervised PCA (Principal Component Analysis) andNMF dimensionality reductions are compared to univariate during the grid search

Additionally Pipeline can be instantiated with the memory argument to memoize the transformers within the pipeline avoiding to fit again the same transformers over and over

Note that the use of memory to enable caching becomes interesting when the fitting of a transformer is costly

Illustration of Pipeline andGridSearchCV

This section illustrates the use of a Pipeline withGridSearchCV

Caching transformers within a Pipeline
It is sometimes worthwhile storing the state of a specific transformer since it could be used again Using a
pipeline inGridSearchCV triggers such situations Therefore we use the argument memory to enable
caching
920 Chapter 5 Examples
```

scikitlearn user guide Release 0213

Warning Note that this example is however only an illustration since for this specific case fitting PCA (Principal Component Analysis) is not necessarily slower than loading the cache Hence use the memory constructor parameter when the fitting of a transformer is costly

```
from tempfile import mkdtemp
from shutil import rmtree
from joblib import Memory

# Create a temporary folder to store the transformers of the pipeline
cachedir = mkdtemp()
memory = Memory(location=cachedir, verbose=10)
cachedpipe = Pipeline(reducedim=PCA(Principal Component Analysis))
classify = LinearSVC(dual=False, max_iter=10000)
memory.memory

# This time a cached pipeline will be used within the grid search
grid = GridSearchCV(cachedpipe, cv=5, n_jobs=1, param_grid=param_grid, iid=False)
digits = load_digits()
grid.fit(digits.data, digits.target)

# Delete the temporary cache before exiting
rmtree(cachedir)
Out
```

ThePCA fitting is only computed at the evaluation of the first configuration of the Cparameter of the LinearSVC classifier The other configurations of Cwill trigger the loading of the cached PCA (Principal Component Analysis) estimator data leading to save processing time Therefore the use of caching the pipeline using memory is highly beneficial when fitting a transformer is costly

Total running time of the script 0 minutes 20695 seconds

575 Column Transformer with Heterogeneous Data Sources

Datasets can often contain components of that require different feature extraction and processing pipelines This scenario might occur when

1 Your dataset consists of heterogeneous data types eg raster images and text captions

2 Your dataset is stored in a Pandas DataFrame and different columns require different processing pipelines

This example demonstrates how to use sklearncomposeColumnTransformer on a dataset containing different types of features We use the 20newsgroups dataset and compute standard bagofwords features for the subject line and body in separate pipelines as well as ad hoc features on the body We combine them with weights using a ColumnTransformer and finally train a classifier on the combined set of features

The choice of features is not particularly helpful but serves to illustrate the technique

576 Effect of transforming the targets in regression model

In this example we give an overview of the `sklearn.compose.TransformedTargetRegressor`. Two examples illustrate the benefit of transforming the targets before learning a linear regression model. The first example uses synthetic data while the second example is based on the Boston housing data set.

Author: Guillaume Lemaître, [guillaumelemaître@nria.fr](#)

License: BSD (Binary Search Decision) 3 clause

```
import numpy as np
import matplotlib
import matplotlib.pyplot as plt
from distutils.version import LooseVersion
printdoc
Synthetic example
from sklearn.datasets import make_regression
from sklearn.model_selection import train_test_split
from sklearn.linear_model import RidgeCV
from sklearn.compose import TransformedTargetRegressor
from sklearn.metrics import median_absolute_error, r2_score
# normed is being deprecated in favor of density in histograms
if LooseVersion(matplotlib.__version__) < 2.1:
    density_param = density = True
else:
    density_param = normed = True
```

A synthetic random regression problem is generated. The targets y are modified by i translating all targets such that all entries are nonnegative and ii applying an exponential function to obtain nonlinear targets which cannot be fitted using a simple linear model.

Therefore a logarithmic `np.log1p` and an exponential function `np.exp(m1)` will be used to transform the targets before training a linear regression model and using it for prediction.

```
X, y = make_regression(n_samples=10000, noise=100, random_state=0)
y = npexp(y) - abs(y.min())
y_trans = nplog1p(y)
```

The following illustrate the probability density functions of the target before and after applying the logarithmic functions.

```
fig, (ax0, ax1) = plt.subplots(1, 2)
ax0.hist(y, bins=100, density_param)
ax0.set_xlim(0, 2000)
ax0.set_ylabel('Probability')
ax0.set_xlabel('Target')
ax0.set_title('Target distribution')
ax1.hist(y_trans, bins=100, density_param)
ax1.set_ylabel('Probability')
```

```

Realworld data set

In a similar manner the boston housing data set is used to show the impact of transforming the targets before learning a model In this example the targets to be predicted corresponds to the weighted distances to the five Boston employment centers

```
from sklearn.datasets import load_boston
from sklearn.preprocessing import QuantileTransformer, quantile_transform
dataset = load_boston
target = np.array(dataset.feature_names == 'DIS')
X = dataset.data[:, np.logical_not(target)]
y = dataset.data[target].squeeze()
ytrans = quantile_transform(dataset.data[target],
                             nquantiles=300,
                             output_distribution='normal',
                             copy=True).squeeze()
# sklearn.preprocessing.QuantileTransformer is used such that the targets follows a normal distribution before applying a sklearn.linear_model.RidgeCV model
fig, (ax0, ax1) = plt.subplots(1, 2)
ax0.hist(y, bins=100, density=True)
ax0.set_ylabel('Probability')
ax0.set_xlabel('Target')
ax0.set_title('Target distribution')
ax1.hist(ytrans, bins=100, density=True)
ax1.set_ylabel('Probability')
ax1.set_xlabel('Target')
ax1.set_title('Transformed target distribution')
fig.suptitle('Boston housing data distance to employment centers')
fig.tight_layout()
X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=1)
```

scikitlearn user guide Release 0213

The effect of the transformer is weaker than on the synthetic data However the transform induces a decrease of the MAE

581 LedoitWolf vs OAS estimation

The usual covariance maximum likelihood estimate can be regularized using shrinkage Ledoit and Wolf proposed a close formula to compute the asymptotically optimal shrinkage parameter minimizing a MSE criterion yielding the LedoitWolf covariance estimate

Chen et al proposed an improvement of the LedoitWolf shrinkage parameter the OAS coefficient whose convergence is significantly better under the assumption that the data are Gaussian

This example inspired from Chen’s publication 1 shows a comparison of the estimated MSE of the LW and OAS methods using Gaussian distributed data

1 “Shrinkage Algorithms for MMSE Covariance Estimation” Chen et al IEEE Trans on Sign Proc V olume 58 Issue 10 October 2010

582 Sparse inverse covariance estimation

Using the GraphicalLasso estimator to learn a covariance and sparse precision from a small number of samples
To estimate a probabilistic model eg a Gaussian model estimating the precision matrix that is the inverse covariance matrix is as important as estimating the covariance matrix Indeed a Gaussian model is parametrized by the precision matrix

To be in favorable recovery conditions we sample the data from a model with a sparse inverse covariance matrix In addition we ensure that the data is not too much correlated limiting the largest coefficient of the precision matrix and that there are no small coefficients in the precision matrix that cannot be recovered In addition with a small number of observations it is easier to recover a correlation matrix rather than a covariance thus we scale the time series Here the number of samples is slightly larger than the number of dimensions thus the empirical covariance is still invertible However as the observations are strongly correlated the empirical covariance matrix is illconditioned and as a result its inverse –the empirical precision matrix– is very far from the ground truth

If we use l_2 shrinkage as with the LedoitWolf estimator as the number of samples is small we need to shrink a lot As a result the LedoitWolf precision is fairly close to the ground truth precision that is not far from being diagonal but the offdiagonal structure is lost

The l_1 penalized estimator can recover part of this offdiagonal structure It learns a sparse precision It is not able to recover the exact sparsity pattern it detects too many nonzero coefficients However the highest nonzero coefficients of the l_1 estimated correspond to the nonzero coefficients in the ground truth Finally the coefficients of the l_1 precision estimate are biased toward zero because of the penalty they are all smaller than the corresponding ground truth value as can be seen on the figure

Note that the color range of the precision matrices is tweaked to improve readability of the figure The full range of values of the empirical precision is not displayed

The alpha parameter of the GraphicalLasso setting the sparsity of the model is set by internal crossvalidation in the GraphicalLassoCV As can be seen on figure 2 the grid to compute the crossvalidation score is iteratively refined in the neighborhood of the maximum

58 Covariance estimation 947

583 Shrinkage covariance estimation LedoitWolf vs OAS and maxlikelihood

When working with covariance estimation the usual approach is to use a maximum likelihood estimator such as `sklearn.covariance.EmpiricalCovariance`. It is unbiased ie it converges to the true population covariance when given many observations. However it can also be beneficial to regularize it in order to reduce its variance this in turn introduces some bias. This example illustrates the simple regularization used in `ShrunkCovariance` estimators. In particular it focuses on how to set the amount of regularization ie how to choose the bias-variance tradeoff.

Here we compare 3 approaches:

- Setting the parameter by crossvalidating the likelihood on three folds according to a grid of potential shrinkage parameters
- A close formula proposed by Ledoit and Wolf to compute the asymptotically optimal regularization parameter minimizing a MSE criterion yielding the `sklearn.covariance.LedoitWolf` covariance estimate
- An improvement of the LedoitWolf shrinkage the `sklearn.covariance.OAS` proposed by Chen et al

Its convergence is significantly better under the assumption that the data are Gaussian in particular for small samples.

To quantify estimation error we plot the likelihood of unseen data for different values of the shrinkage parameter. We also show the choices by crossvalidation or with the LedoitWolf and OAS estimates.

Note that the maximum likelihood estimate corresponds to no shrinkage and thus performs poorly. The LedoitWolf estimate performs really well as it is close to the optimal and is computationally not costly. In this example the OAS estimate is a bit further away. Interestingly both approaches outperform crossvalidation which is significantly most computationally costly.

584 Robust covariance estimation and Mahalanobis distances relevance

An example to show covariance estimation with the Mahalanobis distances on Gaussian distributed data

For Gaussian distributed data the distance of an observation \mathbf{x} to the mode of the distribution can be computed using its Mahalanobis distance $\sqrt{(\mathbf{x}-\boldsymbol{\mu})^T\boldsymbol{\Sigma}^{-1}(\mathbf{x}-\boldsymbol{\mu})}$ where $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are the location and the covariance of the underlying Gaussian distribution

In practice $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are replaced by some estimates The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set and therefor the corresponding Mahalanobis distances are One would better have to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the data set and that the associated Mahalanobis distances accurately reflect the true organisation of the observations

The Minimum Covariance Determinant estimator is a robust highbreakdown point ie it can be used to estimate the covariance matrix of highly contaminated datasets up to $\frac{n-p}{2}$ samples – $\frac{p}{2}$ features – 1

2 outliers estimator of covariance The idea is

to find $\frac{n-p}{2}$ samples $\frac{p}{2}$ features 1

2 observations whose empirical covariance has the smallest determinant yielding a “pure” subset

of observations from which to compute standards estimates of location and covariance

The Minimum Covariance Determinant estimator MCD has been introduced by P J Rousseeuw in 1

This example illustrates how the Mahalanobis distances are affected by outlying data observations drawn from a contaminating distribution are not distinguishable from the observations coming from the real Gaussian distribution

that one may want to work with Using MCD based Mahalanobis distances the two populations become distinguish

able Associated applications are outliers detection observations ranking clustering For visualization purpose

the cubic root of the Mahalanobis distances are represented in the boxplot as Wilson and Hilferty suggest 2

585 Robust vs Empirical covariance estimate
The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set In such a case it would be better to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the data set12
Minimum Covariance Determinant Estimator
The Minimum Covariance Determinant estimator is a robust highbreakdown point ie it can be used to estimate the covariance matrix of highly contaminated datasets up to $\frac{n - \sqrt{n}}{2}$ samples – $\frac{p - \sqrt{p}}{2}$ features – 1
2outliers estimator of covariance The idea is to find $\frac{n - \sqrt{n}}{2}$ samples $\frac{p - \sqrt{p}}{2}$ features1
2observations whose empirical covariance has the smallest determinant yielding a “pure” subset of observations from which to compute standard estimates of location and covariance After a correction step aiming at compensating the fact that the estimates were learned from only a portion of the initial data we end up with robust estimates of the data set location and covariance
The Minimum Covariance Determinant estimator MCD has been introduced by PJRousseeuw in3
Evaluation
In this example we compare the estimation errors that are made when using various types of location and covariance estimates on contaminated Gaussian distributed data sets
• The mean and the empirical covariance of the full dataset which break down as soon as there are outliers in the data set
• The robust MCD that has a low error provided $\frac{n - \sqrt{n}}{2}$ samples 5 $\frac{p - \sqrt{p}}{2}$ features
• The mean and the empirical covariance of the observations that are known to be good ones This can be considered as a “perfect” MCD estimation so one can trust our implementation by comparing to this case

5104 Plot randomly generated multilabel dataset

This illustrates the datasetsmakemultilabelclassification dataset generator Each sample consists of counts of two features up to 50 in total which are differently distributed in each of two classes Points are labeled as follows where Y means the class is present

510 Dataset examples 967

scikitlearn user guide Release 0213

123Color
Y N N Red
N Y N Blue
N N Y Yellow
Y Y N Purple
Y N Y Orange
Y Y N Green
Y Y Y Brown

A star marks the expected sample for each class its size reflects the probability of selecting that class label
The left and right examples highlight the nlabels parameter more of the samples in the right plot have 2 or 3 labels
Note that this twodimensional example is very degenerate generally the number of features would be much greater than the “document length” while here we have much larger documents than vocabulary Similarly with nclasses nfeatures it is much less likely that a feature distinguishes a particular class

5113 Incremental PCA (Principal Component Analysis)

Incremental principal component analysis IPCA is typically used as a replacement for principal component analysis

PCA (Principal Component Analysis) when the dataset to be decomposed is too large to fit in memory IPCA builds a lowrank approximation for the input data using an amount of memory which is independent of the number of input data samples It is still dependent on the input data features but changing the batch size allows for control of memory usage

This example serves as a visual check that IPCA is able to find a similar projection of the data to PCA (Principal Component Analysis) to a sign flip while only processing a few samples at a time This can be considered a “toy example” as IPCA is intended for large datasets which do not fit in main memory requiring incremental approaches

5114 Comparison of LDA and PCA (Principal Component Analysis) 2D projection of Iris dataset
The Iris dataset represents 3 kind of Iris flowers Setosa Versicolour and Virginica with 4 attributes sepal length
sepal width petal length and petal width
Principal Component Analysis PCA (Principal Component Analysis) applied to this data identifies the combination of attributes principal compo
nents or directions in the feature space that account for the most variance in the data Here we plot the different
samples on the 2 first principal components
Linear Discriminant Analysis LDA tries to identify attributes that account for the most variance between classes In
particular LDA in contrast to PCA (Principal Component Analysis) is a supervised method using known class labels

5117 FastICA on 2D point clouds

This example illustrates visually in the feature space a comparison by results using two different component analysis techniques

Independent component analysis ICA vsPrincipal component analysis PCA (Principal Component Analysis)

Representing ICA in the feature space gives the view of ‘geometric ICA’ ICA is an algorithm that finds directions in the feature space corresponding to projections with high nonGaussianity These directions need not be orthogonal in the original feature space but they are orthogonal in the whitened feature space in which all directions correspond to the same variance

PCA (Principal Component Analysis) on the other hand finds orthogonal directions in the raw feature space that correspond to directions accounting for maximum variance

Here we simulate independent sources using a highly nonGaussian process 2 student T with a low number of degrees

of freedom top left figure We mix them to create observations top right figure In this raw observation space

directions identified by PCA (Principal Component Analysis) are represented by orange vectors We represent the signal in the PCA (Principal Component Analysis)

whitening by the variance corresponding to the PCA (Principal Component Analysis) vectors lower left Running ICA corresponds to finding a

rotation in this space to identify the directions of largest nonGaussianity lower right

scikitlearn user guide Release 0213

5119 Model selection with Probabilistic PCA (Principal Component Analysis) and Factor Analysis FA

Probabilistic PCA (Principal Component Analysis) and Factor Analysis are probabilistic models The consequence is that the likelihood of new data can be used for model selection and covariance estimation Here we compare PCA (Principal Component Analysis) and FA with crossvalidation on low rank data corrupted with homoscedastic noise noise variance is the same for each feature or heteroscedastic noise noise variance is the different for each feature In a second step we compare the model likelihood to the likelihoods obtained from shrinkage covariance estimators

One can observe that with homoscedastic noise both FA and PCA (Principal Component Analysis) succeed in recovering the size of the low rank subspace The likelihood with PCA (Principal Component Analysis) is higher than FA in this case However PCA (Principal Component Analysis) fails a when heteroscedastic noise is present Under appropriate circumstances the low rank models are more likely than shrinkage models

The automatic estimation from Automatic Choice of Dimensionality for PCA (Principal Component Analysis) NIPS 2000 598604 by Thomas P Minka is also compared

51110 Sparse coding with a precomputed dictionary
Transform a signal as a sparse combination of Ricker wavelets This example visually compares different sparse coding
methods using the sklearndecompositionSparseCoder estimator The Ricker also known as Mexican
hat or the second derivative of a Gaussian is not a particularly good kernel to represent piecewise constant signals
like this one It can therefore be seen how much adding different widths of atoms matters and it therefore motivates
learning the dictionary to best fit your type of signals
The richer dictionary on the right is not larger in size heavier subsampling is performed in order to stay on the same
order of magnitude

scikitlearn user guide Release 0213

51111 Image denoising using dictionary learning

An example comparing the effect of reconstructing noisy fragments of a raccoon face image using firstly online Dictionary Learning and various transform methods

The dictionary is fitted on the distorted left half of the image and subsequently used to reconstruct the right half Note that even better performance could be achieved by fitting to an undistorted ie noiseless image but here we start from the assumption that it is not available

A common practice for evaluating the results of image denoising is by looking at the difference between the reconstruction and the original image If the reconstruction is perfect this will look like Gaussian noise

It can be seen from the plots that the results of Orthogonal Matching Pursuit OMP with two nonzero coefficients is a bit less biased than when keeping only one the edges look less prominent It is in addition closer from the ground truth in Frobenius norm

The result of Least Angle Regression is much more strongly biased the difference is reminiscent of the local intensity value of the original image

Thresholding is clearly not useful for denoising but it is here to show that it can produce a suggestive output with very high speed and thus be useful for other tasks such as object classification where performance is not necessarily related to visualisation

5125 IsolationForest example

An example using sklearnensembleIsolationForest for anomaly detection

The IsolationForest ‘isolates’ observations by randomly selecting a feature and then randomly selecting a split value

between the maximum and minimum values of the selected feature

Since recursive partitioning can be represented by a tree structure the number of splittings required to isolate a sample

is equivalent to the path length from the root node to the terminating node

This path length averaged over a forest of such random trees is a measure of normality and our decision function

Random partitioning produces noticeable shorter paths for anomalies Hence when a forest of random trees collec

tively produce shorter path lengths for particular samples they are highly likely to be anomalies

1024 Chapter 5 Examples

```
scikitlearn user guide Release 0213
printdoc
import numpy as np
import matplotlib.pyplot as plt
from sklearnensemble import IsolationForest
rng = np.random.RandomState(42)
Generate train data
X = 0.3 * rng.randn(100, 2)

5127 Comparing random forests and the multioutput meta estimator

An example to compare multioutput regression with random forest and the multioutputMultiOutputRegressor meta estimator

This example illustrates the use of the multioutputMultiOutputRegressor metaestimator to perform multioutput regression A random forest regressor is used which supports multioutput regression natively so the results can be compared

The random forest regressor will only ever predict values within the range of observations or closer to zero for each of the targets As a result the predictions are biased towards the centre of the circle

Using a single underlying feature the model learns both the x and y coordinate as output

5129 Gradient Boosting regularization
Illustration of the effect of different regularization strategies for Gradient Boosting The example is taken from Hastie
et al 20091
1T Hastie R Tibshirani and J Friedman “Elements of Statistical Learning Ed 2” Springer 2009
1032 Chapter 5 Examples
```

scikitlearn user guide Release 0213

The loss function used is binomial deviance Regularization via shrinkage learningrate 10 improves performance considerably In combination with shrinkage stochastic gradient boosting subsample 10 can produce more accurate models by reducing the variance via bagging Subsampling without shrinkage usually does poorly Another strategy to reduce the variance is by subsampling the features analogous to the random splits in Random Forests via the maxfeatures parameter

51210 Plot class probabilities calculated by the VotingClassifier

Plot the class probabilities of the first sample in a toy dataset predicted by three different classifiers and averaged by the VotingClassifier

First three exemplary classifiers are initialized: LogisticRegression, GaussianNB, and RandomForestClassifier, and used to initialize a softvoting VotingClassifier with weights [1, 1, 5], which means that the predicted probabilities of the RandomForestClassifier count 5 times as much as the weights of the other classifiers when the averaged probability is calculated

To visualize the probability weighting we fit each classifier on the training set and plot the predicted class probabilities

51212 Two-class AdaBoost

This example fits an AdaBoosted decision stump on a nonlinearly separable classification dataset composed of two “Gaussian quantiles” clusters (see `sklearn.datasets.make_gaussian_quantiles`) and plots the decision boundary and decision scores. The distributions of decision scores are shown separately for samples of class A and B. The predicted class label for each sample is determined by the sign of the decision score. Samples with decision scores greater than zero are classified as B and are otherwise classified as A. The magnitude of a decision score determines the degree of likeness with the predicted class label. Additionally, a new dataset could be constructed containing a desired purity of class B, for example, by only selecting samples with a decision score above some value.

scikitlearn user guide Release 0213
51213 OOB Errors for Random Forests

TheRandomForestClassifier is trained using bootstrap aggregation where each new tree is fit from a bootstrap sample of the training observations. The outofbag OOB error is the average error for each calculated using predictions from the trees that do not contain in their respective bootstrap sample. This allows the RandomForestClassifier to be fit and validated whilst being trained.

The example below demonstrates how the OOB error can be measured at the addition of each new tree during training. The resulting plot allows a practitioner to approximate a suitable value of nestimators at which the error stabilizes.

51214 Hashing feature transformation using Totally Random Trees

RandomTreesEmbedding provides a way to map data to a very highdimensional sparse representation which might be beneficial for classification The mapping is completely unsupervised and very efficient

This example visualizes the partitions given by several trees and shows how the transformation can also be used for nonlinear dimensionality reduction or nonlinear classification

Points that are neighboring often share the same leaf of a tree and therefore share large parts of their hashed representation This allows to separate two concentric circles simply based on the principal components of the transformed data with truncated SVD

In highdimensional spaces linear classifiers often achieve excellent accuracy For sparse binary data BernoulliNB is particularly wellsuited The bottom row compares the decision boundary obtained by BernoulliNB in the transformed space with an ExtraTreesClassifier forests learned on the original data

51215 Multiclass AdaBoosted Decision Trees
This example reproduces Figure 1 of Zhu et al1and shows how boosting can improve prediction accuracy on a multi
class problem The classification dataset is constructed by taking a tendimensional standard normal distribution and
defining three classes separated by nested concentric tendimensional spheres such that roughly equal numbers of
samples are in each class quantiles of the 2distribution
The performance of the SAMME and SAMMER1algorithms are compared SAMMER uses the probability estimates
to update the additive model while SAMME uses the classifications only As the example illustrates the SAMMER
algorithm typically converges faster than SAMME achieving a lower test error with fewer boosting iterations The
error of each algorithm on the test set after each boosting iteration is shown on the left the classification error on the
test set of each tree is shown in the middle and the boost weight of each tree is shown on the right All trees have a
weight of one in the SAMMER algorithm and therefore are not shown

51216 Discrete versus Real AdaBoost

This example is based on Figure 102 from Hastie et al 2009¹ and illustrates the difference in performance between the discrete SAMME2 boosting algorithm and real SAMMER boosting algorithm. Both algorithms are evaluated on a binary classification task where the target Y is a nonlinear function of 10 input features.

Discrete SAMME AdaBoost adapts based on errors in predicted class labels, whereas real SAMMER uses the predicted class probabilities.

51217 Early stopping of Gradient Boosting
Gradient boosting is an ensembling technique where several weak learners regression trees are combined to yield a
powerful single model in an iterative fashion
Early stopping support in Gradient Boosting enables us to find the least number of iterations which is sufficient to
build a model that generalizes well to unseen data
The concept of early stopping is simple We specify a validationfraction which denotes the fraction of the
whole dataset that will be kept aside from training to assess the validation loss of the model The gradient boosting
model is trained using the training set and evaluated using the validation set When each additional stage of regression
tree is added the validation set is used to score the model This is continued until the scores of the model in the last
niternochange stages do not improve by atleast tol After that the model is considered to have converged
and further addition of stages is “stopped early”
The number of stages of the final model is available at the attribute nestimators
This example illustrates how the early stopping can used in the sklearnensemble
GradientBoostingClassifier model to achieve almost the same accuracy as compared to a model
built without early stopping using many fewer estimators This can significantly reduce training time memory usage
and prediction latency

51218 Feature transformations with ensembles of trees

Transform your features into a higher dimensional sparse space Then train a linear model on these features

First fit an ensemble of trees totally random trees a random forest or gradient boosted trees on the training set Then each leaf of each tree in the ensemble is assigned a fixed arbitrary feature index in a new feature space These leaf indices are then encoded in a onehot fashion

Each sample goes through the decisions of each tree of the ensemble and ends up in one leaf per tree The sample is encoded by setting feature values for these leaves to 1 and the other feature values to 0

The resulting transformer has then learned a supervised sparse highdimensional categorical embedding of the data

5.12.19 Gradient Boosting Out-of-Bag estimates

Out-of-bag (OOB) estimates can be a useful heuristic to estimate the “optimal” number of boosting iterations. OOB estimates are almost identical to cross-validation estimates but they can be computed on-the-fly without the need for repeated model fitting. OOB estimates are only available for Stochastic Gradient Boosting (ie. subsample = 1). The estimates are derived from the improvement in loss based on the examples not included in the bootstrap sample (the so-called out-of-bag examples). The OOB estimator is a pessimistic estimator of the true test loss but remains a fairly good approximation for a small number of trees.

The figure shows the cumulative sum of the negative OOB improvements as a function of the boosting iteration. As you can see, it tracks the test loss for the first hundred iterations but then diverges in a pessimistic way. The figure also shows the performance of 3-fold cross-validation, which usually gives a better estimate of the test loss but is computationally more demanding.

51220 Single estimator versus bagging biasvariance decomposition
This example illustrates and compares the biasvariance decomposition of the expected mean squared error of a single
estimator against a bagging ensemble
In regression the expected mean squared error of an estimator can be decomposed in terms of bias variance and
noise On average over datasets of the regression problem the bias term measures the average amount by which the
predictions of the estimator differ from the predictions of the best possible estimator for the problem ie the Bayes
model The variance term measures the variability of the predictions of the estimator when fit over different instances
LS of the problem Finally the noise measures the irreducible part of the error which is due the variability in the data
The upper left figure illustrates the predictions in dark red of a single decision tree trained over a random dataset LS
the blue dots of a toy 1d regression problem It also illustrates the predictions in light red of other single decision
512 Ensemble methods 1061
```

scikitlearn user guide Release 0213

trees trained over other and different randomly drawn instances LS of the problem Intuitively the variance term here corresponds to the width of the beam of predictions in light red of the individual estimators The larger the variance the more sensitive are the predictions for xto small changes in the training set The bias term corresponds to the difference between the average prediction of the estimator in cyan and the best possible model in dark blue On this problem we can thus observe that the bias is quite low both the cyan and the blue curves are close to each other while the variance is large the red beam is rather wide

The lower left figure plots the pointwise decomposition of the expected mean squared error of a single decision tree It confirms that the bias term in blue is low while the variance is large in green It also illustrates the noise part of the error which as expected appears to be constant and around 001

The right figures correspond to the same plots but using instead a bagging ensemble of decision trees In both figures we can observe that the bias term is larger than in the previous case In the upper right figure the difference between the average prediction in cyan and the best possible model is larger eg notice the offset around x2 In the lower right figure the bias curve is also slightly higher than in the lower left figure In terms of variance however the beam of predictions is narrower which suggests that the variance is lower Indeed as the lower right figure confirms the variance term in green is lower than for single decision trees Overall the bias variance decomposition is therefore no longer the same The tradeoff is better for bagging averaging several decision trees fit on bootstrap copies of the dataset slightly increases the bias term but allows for a larger reduction of the variance which results in a lower overall mean squared error compare the red curves int the lower figures The script output also confirms this intuition The total error of the bagging ensemble is lower than the total error of a single decision tree and this difference indeed mainly stems from a reduced variance

For further details on biasvariance decomposition see section 73 of1

51221 Plot the decision surfaces of ensembles of trees on the iris dataset

Plot the decision surfaces of forests of randomized trees trained on pairs of features of the iris dataset

This plot compares the decision surfaces learned by a decision tree classifier first column by a random forest classifier second column by an extra trees classifier third column and by an AdaBoost classifier fourth column

In the first row the classifiers are built using the sepal width and the sepal length features only on the second row using the petal length and sepal length only and on the third row using the petal width and the petal length only

In descending order of quality when trained outside of this example on all 4 features using 30 estimators and scored using 10 fold cross validation we see

ExtraTreesClassifier 095 score

RandomForestClassifier 094 score

AdaBoostDecisionTreemaxdepth3 094 score

DecisionTreemaxdepth None 094 score

Increasing maxdepth for AdaBoost lowers the standard deviation of the scores but the average score does not improve

See the console's output for further details about each model

In this example you might try to

1 vary the maxdepth for the DecisionTreeClassifier andAdaBoostClassifier perhaps try maxdepth3 for theDecisionTreeClassifier ormaxdepthNone for

AdaBoostClassifier

2 varynestimators

It is worth noting that RandomForests and ExtraTrees can be fitted in parallel on many cores as each tree is built independently of the others AdaBoost's samples are built sequentially and so do not use multiple cores

Answer to the bonus question how much can you trust the selection of alpha
Alpha parameters maximising the generalization score on different
subsets of the data

fold 0 alpha 005968 score 054209

fold 1 alpha 004520 score 015523

fold 2 alpha 007880 score 045193

Answer Not very much since we obtained different alphas for different
subsets of the data and moreover the scores for these alphas differ
quite substantially

printdoc

import numpy as np

import matplotlib.pyplot as plt

from sklearn import datasets

from sklearn.linear_model import LassoCV

513 Tutorial exercises 1077

```
scikitlearn user guide Release 0213
from sklearn.linear_model import Lasso
from sklearn.model_selection import KFold
from sklearn.model_selection import GridSearchCV
diabetes = datasets.load_diabetes
X = diabetes.data[150:]
y = diabetes.target[150:]
lasso = Lasso(random_state=0, max_iter=10000)
alphas = np.logspace(-4, 0, 30)
tuned_parameters = {'alpha': alphas}
n_folds = 5
clf = GridSearchCV(lasso, tuned_parameters, cv=kf, refit=False)
clf.fit(X, y)
scores = clf.cv_results_['mean_test_score']
scores_std = clf.cv_results_['std_test_score']
plt.figure(figsize=(8, 6))
plt.semilogx(alphas, scores)
    plot error lines showing std errors of the scores
std_err = scores_std / np.sqrt(n_folds)
plt.semilogx(alphas, scores, std_err, b)
plt.semilogx(alphas, scores, std_err, b)
    alpha=0.2 controls the translucency of the fill color
plt.fill_between(alphas, scores, std_err, alpha=0.2)
plt.ylabel('CV score (std error)')
plt.xlabel('alpha')
plt.xticks(np.logspace(-4, 0, 5))
plt.xlim(alphas[0], alphas[-1])
```

Bonus: how much can you trust the selection of alpha?

To answer this question, we use the `LassoCV` object that sets its alpha parameter automatically from the data by internal cross-validation, i.e. it performs cross-validation on the training data it receives.

We use external cross-validation to see how much the automatically obtained alphas differ across different cross-validation folds.

```
lasso_cv = LassoCV(alphas=alphas, cv=5, random_state=0, max_iter=10000)
kf = KFold(3)
print Answer to the bonus question:
    how much can you trust the selection of alpha?
print
print Alpha parameters maximising the generalization score on different
    subsets of the data:
for train, test in enumerate(kf.split(X, y)):
    lasso_cv.fit(X[train], y[train])
    print fold %d, alpha: %f, score: %f % (fold, alphas[lasso_cv.alpha_], lasso_cv.score(X[test], y[test]))
print
print Answer: Not very much, since we obtained different alphas for different
    subsets of the data, and moreover, the scores for these alphas differ.

5142 Comparison of Ftest and mutual information
This example illustrates the differences between univariate Ftest statistics and mutual information.
We consider 3 features x1, x2, x3 distributed uniformly over [0, 1]. The target depends on them as follows:
y = x1 * sin(6 * pi * x2) * 0.1 + N(0, 1) that is the third feature is completely irrelevant.
The code below plots the dependency of y against individual xi and normalized values of univariate Ftests statistics
and mutual information.
As Ftest captures only linear dependency, it rates x1 as the most discriminative feature. On the other hand, mutual
information can capture any kind of dependency between variables and it rates x2 as the most discriminative feature,
which probably agrees better with our intuitive perception for this example. Both methods correctly mark x3 as
irrelevant.
```

5147 Univariate Feature Selection

An example showing univariate feature selection

Noisy non informative features are added to the iris data and univariate feature selection is applied For each feature we plot the pvalues for the univariate feature selection and the corresponding weights of an SVM (Support Vector Machine) We can see that univariate feature selection selects the informative features and that these have larger SVM (Support Vector Machine) weights In the total set of features only the 4 first ones are significant We can see that they have the highest score with univariate feature selection The SVM (Support Vector Machine) assigns a large weight to one of these features but also Selects many of the noninformative features Applying univariate feature selection before the SVM (Support Vector Machine) increases the SVM (Support Vector Machine)

5153 Comparison of kernel ridge and Gaussian process regression

Both kernel ridge regression KRR and Gaussian process regression GPR learn a target function by employing internally the “kernel trick” KRR learns a linear function in the space induced by the respective kernel which corresponds to a nonlinear function in the original space The linear function in the kernel space is chosen based on the meansquared error loss with ridge regularization GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function Based on Bayes theorem a Gaussian posterior distribution over target functions is defined whose mean is used for prediction A major difference is that GPR can choose the kernel’s hyperparameters based on gradientascent on the marginal likelihood function while KRR needs to perform a grid search on a crossvalidated loss function meansquared error loss A further difference is that GPR learns a generative probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions

This example illustrates both methods on an artificial dataset which consists of a sinusoidal target function and strong noise The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel which is suited for learning periodic functions The kernel’s hyperparameters control the smoothness l and periodicity of the kernel p Moreover the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR

The figure shows that both methods learn reasonable models of the target function GPR correctly identifies the periodicity of the function to be roughly 2pi 628 while KRR chooses the doubled periodicity 4pi Besides that GPR provides reasonable confidence bounds on the prediction which are not available for KRR A major difference between the two methods is the time required for fitting and predicting while fitting KRR is fast in principle the gridsearch for hyperparameter optimization scales exponentially with the number of hyperparameters “curse of dimensional ity” The gradientbased optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerable faster on this example with 3dimensional hyperparameter space The time for predicting is similar however generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean

5156 Probabilistic predictions with Gaussian process classification GPC

This example illustrates the predicted probability of GPC for an RBF (Radial Basis Function) kernel with different choices of the hyperparameters The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum logmarginallikelihood LML

While the hyperparameters chosen by optimizing LML have a considerable larger LML they perform slightly worse according to the logloss on test data The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries which is good but have predicted probabilities close to 05 far away from the class boundaries which is bad This undesirable effect is caused by the Laplace approximation used internally by GPC

The second figure shows the logmarginallikelihood for different choices of the kernel’s hyperparameters highlighting the two choices of the hyperparameters used in the first figure by black dots

5157 Gaussian process regression GPR with noiselevel estimation

This example illustrates that GPR with a sumkernel including a WhiteKernel can estimate the noise level of data
An illustration of the logmarginallikelihood LML landscape shows that there exist two local maxima of LML The
first corresponds to a model with a high noise level and a large length scale which explains all variations in the data
by noise The second one has a smaller noise level and shorter length scale which explains most of the variation by
the noisefree functional relationship The second model has a higher likelihood however depending on the initial
value for the hyperparameters the gradientbased optimization might also converge to the highnoise solution It is
thus important to repeat the optimization several times for different initializations

5158 Gaussian Processes regression basic introductory example

A simple onedimensional regression example computed in two different ways

1 A noisefree case

2 A noisy case with known noiselevel per datapoint

In both cases the kernel's parameters are estimated using the maximum likelihood principle

The figures illustrate the interpolating property of the Gaussian Process model as well as its probabilistic nature in the form of a pointwise 95 confidence interval

Note that the parameter alpha is applied as a Tikhonov regularization of the assumed covariance between the training points

5159 Gaussian process regression GPR on Mauna Loa CO2 data

This example is based on Section 543 of “Gaussian Processes for Machine Learning” RW2006 It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the logmarginal likelihood The data consists of the monthly average atmospheric CO2 concentrations in parts per million by volume ppmv collected at the Mauna Loa Observatory in Hawaii between 1958 and 2001 The objective is to model the CO2 concentration as a function of the time t

The kernel is composed of several terms that are responsible for explaining different properties of the signal

- a long term smooth rising trend is to be explained by an RBF (Radial Basis Function) kernel The RBF (Radial Basis Function) kernel with a large lengthscale enforces this component to be smooth it is not enforced that the trend is rising which leaves this choice to the GP The specific lengthscale and the amplitude are free hyperparameters

- a seasonal component which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year The lengthscale of this periodic component controlling its smoothness is a free parameter In order to allow decaying away from exact periodicity the product with an RBF (Radial Basis Function) kernel is taken The lengthscale of this RBF (Radial Basis Function) component controls the decay time and is a further free parameter

- smaller medium term irregularities are to be explained by a RationalQuadratic kernel component whose lengthscale and alpha parameter which determines the diffuseness of the lengthscales are to be determined According to RW2006 these irregularities can better be explained by a RationalQuadratic than an RBF (Radial Basis Function) kernel component probably because it can accommodate several lengthscales

- a “noise” term consisting of an RBF (Radial Basis Function) kernel contribution which shall explain the correlated noise components such as local weather phenomena and a WhiteKernel contribution for the white noise The relative amplitudes and the RBF (Radial Basis Function)’s length scale are further free parameters

Maximizing the logmarginallikelihood after subtracting the target’s mean yields the following kernel with an LML of 83214

3442RBFlengthscale418

3272RBFlengthscale180 ExpSineSquaredlengthscale144 periodicity1

04462RationalQuadraticalpha177 lengthscale0957

01972RBFlengthscale0138 WhiteKernelnoiselevel00336

Thus most of the target signal 344ppm is explained by a longterm rising trend lengthscale 418 years The periodic component has an amplitude of 327ppm a decay time of 180 years and a lengthscale of 144 The long decay time indicates that we have a locally very close to periodic seasonal component The correlated noise has an amplitude of 0197ppm with a length scale of 0138 years and a whitenoise contribution of 0197ppm Thus the 1116 Chapter 5 Examples

scikitlearn user guide Release 0213

overall noise level is very small indicating that the data can be very well explained by the model The figure shows also that the model makes very confident predictions until around 2015

516 Missing Value Imputation

Examples concerning the sklearnimpute module

Note Click here to download the full example code

5161 Imputing missing values with variants of IterativeImputer

The sklearnimpute.IterativeImputer class is very flexible it can be used with a variety of estimators

to do roundrobin regression treating every variable as an output in turn

In this example we compare some estimators for the purpose of missing feature imputation with sklearnimpute

IterativeImputer

- BayesianRidge regularized linear regression

516 Missing Value Imputation 1119

scikitlearn user guide Release 0213

- DecisionTreeRegressor nonlinear regression
- ExtraTreesRegressor similar to missForest in R
- KNeighborsRegressor comparable to other KNN imputation approaches

Of particular interest is the ability of sklearnimputeIterativeImputer to mimic the behavior of missForest a popular imputation package for R In this example we have chosen to use sklearnensembleExtraTreesRegressor instead of sklearnensembleRandomForestRegressor as in missForest due to its increased speed

Note that sklearnneighborsKNeighborsRegressor is different from KNN imputation which learns from samples with missing values by using a distance metric that accounts for missing values rather than imputing them

The goal is to compare different estimators to see which one is best for the sklearnimputeIterativeImputer when using a sklearnlinearmodelBayesianRidge estimator on the California housing dataset with a single value randomly removed from each row

For this particular pattern of missing values we see that sklearnensembleExtraTreesRegressor and sklearnlinearmodelBayesianRidge give the best results

5162 Imputing missing values before building an estimator

Missing values can be replaced by the mean, the median, or the most frequent value using the basic sklearn `impute.SimpleImputer`. The median is a more robust estimator for data with high magnitude variables which could dominate results otherwise known as a ‘long tail’.

Another option is the sklearn `impute.IterativeImputer`. This uses round-robin linear regression treating every variable as an output in turn. The version implemented assumes Gaussian output variables. If your features are obviously non-normal, consider transforming them to look more normal so as to potentially improve performance. In addition to using an imputing method, we can also keep an indication of the missing information using sklearn `impute.MissingIndicator` which might carry some information.

5171 Partial Dependence Plots
Partial dependence plots show the dependence between the target function2and a set of ‘target’ features marginalizing
over the values of all other features the complement features Due to the limits of human perception the size of the
target feature set must be small usually one or two thus the target features are usually chosen among the most
important features
This example shows how to obtain partial dependence plots from a MLPRegressor and a
GradientBoostingRegressor trained on the California housing dataset The example is taken from1
The plots show four 1way and two 1way partial dependence plots omitted for MLPRegressor due to computa
tion time The target variables for the oneway PDP are median income MedInc average occupants per household
AvgOccup median house age HouseAge and average rooms per household AveRooms
2For classification you can think of it as the regression score before the link function
1T Hastie R Tibshirani and J Friedman “Elements of Statistical Learning Ed 2” Springer 2009
517 Inspection 1125
```

scikitlearn user guide Release 0213

We can clearly see that the median house price shows a linear relationship with the median income top left and that the house price drops when the average occupants per household increases top middle The top right plot shows that the house age in a district does not have a strong influence on the median house price so does the average rooms per household The tick marks on the xaxis represent the deciles of the feature values in the training data We also observe that MLPRegressor has much smoother predictions than GradientBoostingRegressor For the plots to be comparable it is necessary to subtract the average value of the target y The 'recursion' method used by default for GradientBoostingRegressor does not account for the initial predictor in our case the average target Setting the target average to 0 avoids this bias

Partial dependence plots with two target features enable us to visualize interactions among them The twoway partial dependence plot shows the dependence of median house price on joint values of house age and average occupants per household We can clearly see an interaction between the two features for an average occupancy greater than two the house price is nearly independent of the house age whereas for values less than two there is a strong dependence on age

On a third figure we have plotted the same partial dependence plot this time in 3 dimensions

5182 Plot Ridge coefficients as a function of the regularization

Shows the effect of collinearity in the coefficients of an estimator

Ridge Regression is the estimator used in this example Each color represents a different feature of the coefficient

vector and this is displayed as a function of the regularization parameter

This example also shows the usefulness of applying Ridge regression to highly illconditioned matrices For such

matrices a slight change in the target variable can cause huge variances in the calculated weights In such cases it is

useful to set a certain regularization alpha to reduce this variation noise

When alpha is very large the regularization effect dominates the squared loss function and the coefficients tend to

zero At the end of the path as alpha tends toward zero and the solution tends towards the ordinary least squares

coefficients exhibit big oscillations In practise it is necessary to tune alpha in such a way that a balance is maintained

between both

5185 Ordinary Least Squares and Ridge Regression Variance

Due to the few points in each dimension and the straight line that linear regression uses to follow these points as well as it can noise on the observations will cause great variance as shown in the first plot Every line’s slope can vary quite a bit for each prediction due to the noise induced in the observations
Ridge regression is basically minimizing a penalised version of the leastsquared function The penalising shrinks the value of the regression coefficients Despite the few data points in each dimension the slope of the prediction is much more stable and the variance in the line itself is greatly reduced in comparison to that of the standard linear regression

5186 Plot Ridge coefficients as a function of the L2 regularization

Ridge Regression is the estimator used in this example Each color in the left plot represents one different dimension of the coefficient vector and this is displayed as a function of the regularization parameter The right plot shows how exact the solution is This example illustrates how a well defined solution is found by Ridge regression and how regularization affects the coefficients and their values The plot on the right shows how the difference of the coefficients from the estimator changes as a function of regularization

In this example the dependent variable Y is set as a function of the input features $y = Xw + c$ The coefficient vector w is randomly sampled from a normal distribution whereas the bias term c is set to a constant

As α tends toward zero the coefficients found by Ridge regression stabilize towards the randomly sampled vector w For big α strong regularisation the coefficients are smaller eventually converging at 0 leading to a simpler and biased solution These dependencies can be observed on the left plot

The right plot shows the mean squared error between the coefficients found by the model and the chosen vector w Less regularised models retrieve the exact coefficients error is equal to 0 stronger regularised models increase the error

Please note that in this example the data is nonnoisy hence it is possible to extract the exact coefficients

5188 Regularization path of L1 Logistic Regression
Train l1penalized logistic regression models on a binary classification problem derived from the Iris dataset
The models are ordered from strongest regularized to least regularized The 4 coefficients of the models are collected
and plotted as a “regularization path” on the lefthand side of the figure strong regularizers all the coefficients are
exactly 0 When regularization gets progressively looser coefficients can get nonzero values one after the other
Here we choose the SAGA solver because it can efficiently optimize for the Logistic Regression loss with a non
smooth sparsity inducing l1 penalty
Also note that we set a low value for the tolerance to make sure that the model has converged before collecting the
coefficients
We also use warmstartTrue which means that the coefficients of the models are reused to initialize the next model
fit to speedup the computation of the fullpath

5189 Polynomial interpolation

This example demonstrates how to approximate a function with a polynomial of degree ndegree by using ridge regression Concretely from nsamples 1d points it suffices to build the Vandermonde matrix which is nsamples x ndegree1 and has the following form

$$1 \ x_1 \ x_1^2 \ x_1^3 \ \dots \ 1 \ x_2 \ x_2^2 \ x_2^3 \ \dots$$

Intuitively this matrix can be interpreted as a matrix of pseudo features the points raised to some power The matrix is akin to but different from the matrix induced by a polynomial kernel

This example shows that you can do nonlinear regression with a linear model using a pipeline to add nonlinear features Kernel methods extend this idea and can induce very high even infinite dimensional feature spaces

51813 Linear Regression Example

This example uses the only the first feature of the diabetes dataset in order to illustrate a two-dimensional plot of this regression technique. The straight line can be seen in the plot showing how linear regression attempts to draw a straight line that will best minimize the residual sum of squares between the observed responses in the dataset and the responses predicted by the linear approximation. The coefficients, the residual sum of squares and the variance score are also calculated.

51817 HuberRegressor vs Ridge on dataset with strong outliers

Fit Ridge and HuberRegressor on a dataset with outliers

The example shows that the predictions in ridge are strongly influenced by the outliers present in the dataset The Huber regressor is less influenced by the outliers since the model uses the linear loss for these As the parameter epsilon is increased for the Huber regressor the decision function approaches that of the ridge

51818 Joint feature selection with multitask Lasso

The multitask lasso allows to fit multiple regression problems jointly enforcing the selected features to be the same

across tasks This example simulates sequential measurements each task is a time instant and the relevant features

vary in amplitude over time while being the same The multitask lasso imposes that features that are selected at one

time point are select for all time point This makes feature selection by the Lasso more stable

51821 MNIST classification using multinomial logistic L1

Here we fit a multinomial logistic regression with L1 penalty on a subset of the MNIST digits classification task We use the SAGA algorithm for this purpose this a solver that is fast when the number of samples is significantly larger than the number of features and is able to finely optimize nonsmooth objective functions which is the case with the l1penalty Test accuracy reaches 08 while weight vectors remains sparse and therefore more easily interpretable Note that this accuracy of this l1penalized linear model is significantly below what can be reached by an l2penalized linear model or a nonlinear multilayer perceptron model on this dataset

Out

Sparsity with L1 penalty 8080

Test score with L1 penalty 08351

Example run in 28654 s

51824 TheilSen Regression

Computes a TheilSen Regression on a synthetic dataset

SeeTheilSen estimator generalizedmedianbased estimator for more information on the regressor

Compared to the OLS ordinary least squares estimator the TheilSen estimator is robust against outliers It has a breakdown point of about 293 in case of a simple linear regression which means that it can tolerate arbitrary corrupted data outliers of up to 293 in the twodimensional case

The estimation of the model is done by calculating the slopes and intercepts of a subpopulation of all possible combinations of p subsample points If an intercept is fitted p must be greater than or equal to nfeatures + 1 The final slope and intercept is then defined as the spatial median of these slopes and intercepts

In certain cases TheilSen performs better than RANSAC which is also a robust method This is illustrated in the second example below where outliers with respect to the xaxis perturb RANSAC Tuning the residualthreshold

parameter of RANSAC remedies this but in general a priori knowledge about the data and the nature of the outliers

is needed Due to the computational complexity of TheilSen it is recommended to use it only for small problems in

terms of number of samples and features For larger problems the maxsubpopulation parameter restricts the

magnitude of all possible combinations of p subsample points to a randomly chosen subset and therefore also limits the

runtime Therefore TheilSen is applicable to larger problems with the drawback of losing some of its mathematical

properties since it then works on a random subset

51826 Robust linear estimator fitting
Here a sine function is fit with a polynomial of order 3 for values close to zero
Robust fitting is demoed in different situations
1178 Chapter 5 Examples
```

scikitlearn user guide Release 0213

- No measurement errors only modelling errors fitting a sine with a polynomial
- Measurement errors in X
- Measurement errors in y

The median absolute deviation to non corrupt new data is used to judge the quality of the prediction

What we can see that

- RANSAC is good for strong outliers in the y direction
- TheilSen is good for small outliers both in direction X and y but has a break point above which it performs worse than OLS
- The scores of HuberRegressor may not be compared directly to both TheilSen and RANSAC because it does not attempt to completely filter the outliers but lessen their effect

51827 L1 Penalty and Sparsity in Logistic Regression
Comparison of the sparsity percentage of zero coefficients of solutions when L1 L2 and ElasticNet penalty are used
for different values of C We can see that large values of C give more freedom to the model Conversely smaller values
of C constrain the model more In the L1 penalty case this leads to sparser solutions As expected the ElasticNet
penalty sparsity is between that of L1 and L2
We classify 8x8 images of digits into two classes 04 against 59 The visualization shows coefficients of the models
for varying C

51829 Automatic Relevance Determination Regression ARD

Fit regression model with Bayesian Ridge Regression

See Bayesian Ridge Regression for more information on the regressor

Compared to the OLS ordinary least squares estimator the coefficient weights are slightly shifted toward zeros

which stabilises them

The histogram of the estimated weights is very peaked as a sparsity inducing prior is implied on the weights

The estimation of the model is done by iteratively maximizing the marginal loglikelihood of the observations

We also plot predictions and uncertainties for ARD for one dimensional regression using polynomial feature expansion

Note the uncertainty starts going up on the right side of the plot This is because these test samples are outside

of the range of the training samples

51830 Bayesian Ridge Regression

Computes a Bayesian Ridge Regression on a synthetic dataset

SeeBayesian Ridge Regression for more information on the regressor

Compared to the OLS ordinary least squares estimator the coefficient weights are slightly shifted toward zeros which stabilises them
